HEMATINIC PLASTULES

Recovery from hypochromic anemia, in cases treated with Hematinic Plastules, is usually rapid and unrestrained as evidenced by the early increase in the hemoglobin of the red blood cells. The suggested daily dose of only three Hematinic Plastules Plain replaces massive iron feedings and diminishes the likelihood of gastric disturbances, constipation and diarrhea . . . Hematinic Plastules provide ferrous iron and vitamins B and G in soluble gelatin capsules, available in two types, Plain and with Liver Extract. Inquiries from physicians are given prompt attention.

KNOX CLINICAL NOTES

ONE OF A SERIES OF CORRESPONDENCE EXCHANGES WITH PHYSICIANS ABOUT KNOX GELATINE.

QUERY about the Allergic Manifestation of KNOX GELATINE

A doctor writes, "Would you kindly tell me from what sources the materials used in making Knox Gelatine are obtained? I am especially interested in whether or not it is all beef, all pork, all sheep, or a mixture of proteins from different animals; also is the manufacture constant as to the ingredients used? This is very important to me as I want to use it for special diets in allergic cases, and for this purpose the exact sources of a food must be known and unvaried."

Knox Gelatine Laboratory REPLY

Knox Gelatine is scientifically prepared from carefully selected long, hard, shank *beef bones only*. Twenty-one control and laboratory tests are made throughout the process of its manufacture. As far as we know, no case of allergy has ever been traced to the use of Knox Gelatine. Contrariwise, there is reason to believe that when Knox Gelatine is added to milk, patients sensitive to milk will show no allergic response.

Sample and useful Dietary Booklets
on Request Write Dept. 475

A good example of a CONCENTRATED Knox
Gelatine Recipe:

THE KNOX MILK STIR

Place the contents of 4 envelopes of Knox Gelatine in an ordinary drinking glass. Add 4 ounces of cold milk and allow to soak for five minutes. Add 2 more ounces of milk and stir until thoroughly soaked. Then place glass in small cooking kettle of hot water until gelatine milk mixture is thoroughly dissolved. Add 2 more ounces of cold milk, which will bring the temperature to a satisfactory warm drink of about body heat. A tablespoonful of prune juice or a few drops of any bland flavor like vanilla may be added.

Total: 8 oz. liquid—about 250 calories

Why you should insist on Knox Sparkling Gelatine

Because Knox Gelatine is 85% protein in an easily digestible form—because it contains absolutely no sugar or other substances to cause gas or fermentation, Knox Gelatine should not be confused with factory-flavored, sugar-laden dessert powders. Knox is 100% pure U.S.P. gelatine. Knox Gelatine has been successfully used in the dietary of convalescents, anorexia, tubercular, diabetic, colitic, and aged patients.

KNOX SPARKLING GELATINE

IMPORTANT INDICATIONS

for CRYSTALLINE VITAMIN B₁

IT has been definitely established that a deficient intake of vitamin B₁ is not uncommon. Hence, Betaxin (crystalline vitamin B₁ hydrochloride) in small doses is a valuable supplement to the diet of infants and growing children, especially in the presence of malnutrition. Therapeutically it is particularly indicated in patients suffering from loss of appetite, reduced activity of the gastro-intestinal tract (secretory and motor), muscular weakness, polyneuritis due to alcoholism, and pernicious vomiting of pregnancy. Betaxin has also rendered excellent service in the treatment of neuritis, neuralgias and nervous disorders. Since the body does not retain an excess of vitamin B₁, toxic effects are not to be expected even from uncommonly large doses over a prolonged period.

HOW SUPPLIED: Tablets of 0.1 mg., 0.5 mg., and 1 mg., bottles of 50; tablets of 5 mg., bottles of 25. Ampules of 1 mg. (1 cc.), boxes of 10 and 100; ampules of 10 mg. (1 cc.), boxes of 5.

Booklet giving detailed information gladly sent on request.

Usual direction of osmotic force in intestine.

Reversal of osmotic force by Sal Hepatica in solution. Fluid is retained in intestine for production of liquid bulk.

Osmotic Influence

gives **LIQUID BULK** for COLONIC IRRIGATION

THE osmotic influence of Sal Hepatica partially retards absorption of ingested liquids from the intestines. The resultant *fluid bulk* stimulates peristalsis; it lubricates and flushes the intestinal tract to help dispose of undesirable waste. The safety of Sal Hepatica lies in the fact that the added bulk is practically all *water*.

The mineral alkalines of Sal Hepatica aid in neutralizing excessive stomach acidity. They are also efficiently cholagogic, promoting digestion by increasing the flow of bile.

Sal Hepatica simulates the action of famous mineral spring waters. It makes a zestful, effervescent drink. Samples and literature available upon request.

SAL HEPATICA

Flushes the Intestinal Tract and Aids Nature to Combat Gastric Acidity

BELOW—Mucilose stool

IN THE TREATMENT OF

Constipation . . .

Stool Dehydration

Rx

MUCILOSE

Water deficiency—dehydration—is characteristic of the stool in constipation.

Mucilose has proved clinically successful in constipation therapy because it helps to hold water in the feces, tends to preserve the normal fecal colloid and produce a large, soft, pliable stool which is easily expelled.

Mucilose offers a hemicellulose (vegetable gum) prepared by a special process from the *Plantago loellingii*. It is pleasant and easy to take with the result that your patients are ready and willing to follow your prescribed regimen consistently.

Mucilose is available for your prescription in two forms, MUCILOSE GRANULES and MUCILOSE FLAKES.

Your Richest Patient

CANNOT BUY BETTER MILK for his ulcer diet, than is everywhere available at a price your poorest patient can afford to pay.

That is true beyond the possibility of question—for there is no milk more wholesome, more surely safe, and more easily digested than Irradiated Pet Milk.

The processes of concentration, irradiation, homogenization and sterilization give to Pet Milk qualities which make

it especially adaptable to dietary treatment of digestive diseases. No wealth can buy milk with a more suitable combination of qualities—and yet, Pet Milk, because it costs less generally than ordinary milk, is available at a price your poorest patient can afford to pay.

Samples and literature will be mailed on request.

POINTS IN HEMORRHOIDAL THERAPY

Therapeutic effectiveness, safety, absence of accessory or systemic effect, convenience—these are the four points that distinguish ANUSOL SUPPOSITORIES.

Relief of pain and discomfort is attained by decongestion, not by narcotic, analgesic or anesthetic drugs. Anusol Suppositories are protective and soothing, because the ingredients are incorporated in an emollient base. No belladonna, no epinephrin, no ephedrin—nothing that may cause systemic reaction, is contained in Anusol Suppositories. And they are so shaped that introduction could not possibly cause trauma. Every consideration, indeed, suggests the use of Anusol Suppositories for the medical treatment of hemorrhoids. It is therapy that has conclusively proved its value.

SCHERING & GLATZ, INC.

REGULATION

Regulation of the daily program, especially diet and exercise, is beneficial to normal bowel movement and in some cases of constipation serves as sufficient treatment. Others require additional aid to facilitate regular evacuation.

When an adjunct to diet and exercise is required, as it often is, Petrolagar provides a mild but effective treatment. Its miscible

properties make it easier to take and more effective than plain mineral oil. Further, by softening the feces, Petrolagar induces large, well formed stools which are easy to evacuate.

The five types of Petrolagar afford a choice of medication adaptable to the individual patient . . . Petrolagar Laboratories, Inc., 8134 McCormick Blvd., Chicago, Illinois.

Petrolagar — Liquid petrolatum 65 cc. emulsified with 0.4 Gm. agar in a menstruum to make 100 cc.

CRYSTALLINE VITAMIN

THIAMIN CHLORIDE SQUIBB

**AVAILABLE IN AN EXTENDED SERIES OF CONVENIENT,
ECONOMICAL DOSAGE FORMS**

THIAMIN CHLORIDE SQUIBB is indicated in the treatment of all degrees of Vitamin B₁ deficiency, but is especially useful in the more severe forms since it permits accurate massive dosage in small volume.

Where quick results are desired or where gastro-intestinal disease may interfere with absorption from the alimentary canal, Solution Thiamin Chloride Squibb for parenteral administration provides a convenient means of administering dosages from 300 units to 75,000 units *without waste*.

For oral administration — Tablets Thiamin Chloride are convenient to use and palatable. Both the Tablets and Solution are stable and economical.

SOLUTION THIAMIN CHLORIDE SQUIBB
for parenteral administration

5-cc. Rubber-Capped Vials

10 mg. per cc. (3000 I.U. per cc.)

25 mg. per cc. (7500 I.U. per cc.)

50 mg. per cc. (15,000 I.U. per cc.)

1-cc. All-Glass Ampuls

10 mg. per cc. (3000 I.U. per cc.)

Boxes of 6 and 25 ampuls

TABLETS THIAMIN CHLORIDE SQUIBB
for oral administration

1 mg. per tablet (300 I.U. per tablet)

Bottles of 50 and 250 tablets

5 mg. per tablet (1500 I.U. per tablet)

Bottles of 50 tablets

A Comprehensive Treatment for

MUCOUS COLITIS

(“UNSTABLE COLON”)

CLINICALLY TESTED IN OVER 1000 CASES

EXTENSIVE clinical work has proved the value of Soricin, alone or in conjunction with B. Coli Vaccine-Detoxified with Soricin, in treating obstinate cases of these common, but baffling conditions:

Mucous Colitis (“Unstable Colon”)
 Intestinal Toxemia
 Chronic Functional Diarrhea
 Chronic Headaches from Chronic
 Constipation or Colon Distress
 Chronic “toxic vertigo”

This comprehensive plan of therapy is being used most successfully by many physicians. It is completely described in the booklet “The Therapeutic Use of Soricin with Colon Bacillus Vaccine Therapy.” Write for your copy.

• SORICIN •

A special brand of the detoxifying agent, sodium ricinoleate, which has been shown to detoxify intestinal organisms and their filtrates, and to exert an inhibitive action on the proteolytic and putrefactive bacteria in the bowel contents.

Soricin dosage forms include 5 gr. tablets as well as 5 and 10 gr. capsules

B. COLI VACCINE DETOXIFIED with SORICIN

B. Coli Vaccine-Detoxified (Merrell) is prepared from selected strains of B. coli communis (*Escherichia coli*) and B. coli communior (*Escherichia communior*) mixed in equal proportions and detoxified with Soricin (sodium ricinoleate).

Available in a series of dilutions ranging from
 5000 to 1000 million organisms per cc.

Bananas are mentioned frequently in ancient Chinese writings. The fruit was considered a delicacy—the fiber from the stalk used in weaving mats. There is little commercial use for the fiber today, but the fruit is known all over the world as an important staple food.

INTERESTING BANANA FACTS

IT is now recognized that the banana is a serviceable food under a wide range of conditions. As an energy food, which assists by virtue of its mineral and vitamin content in regulating body functions, it is useful in normal diets at all ages. In disease it is suited for some of those conditions in which the maintenance of proper nutrition is especially difficult. It is sometimes helpful under diametrically opposite circumstances—in both overweight and underweight, or in diarrhea and constipation.

The key to the varied usefulness of the banana is to be found in its composition. Special points stand out as qualifying it for inclusion in special types of diets. These are summarized in outline form below:

PROPERTIES OF RIPE BANANA PULP	MAKE IT OF VALUE IN
Readily assimilated sugars (along with vitamins, minerals and fiber).....	Infant Feeding
Caloric value (along with vitamins and minerals)....	Malnutrition
Satiety value and low fat (along with vitamins and minerals).....	Reducing Diets
Alkaline residue	Combating Acidosis
Vitamin content	Preventing Deficiency Diseases
Soft texture and blandness (with carbohydrates, vitamins, minerals, pectin and fiber).....	Intestinal Disturbances
	Normalizing Colonic Function
	Convalescent Diets

PROXIMATE COMPOSITION RIPE BANANA PULP

*Contains important minerals including calcium, copper, iron and phosphorus

What to do about the JITTERY GUT?

For a reliable antispasmodic to relieve gastro-intestinal spasms, you will find non-narcotic TRASENTIN[®], "Ciba" quick-acting and well tolerated. It relieves BOTH neurogenic and myogenic spasms of many smooth muscles without as a rule manifesting toxic effects or undesirable side actions in full therapeutic doses.*

Trasentin (hydrochloride of diphenyl-acetyldiethyl-aminoethanol) may be administered orally, subcutaneously, intramuscularly (or intravenously in emergencies), for relieving spasms of G-I tract, biliary tract, genito-urinary tract.

The Diagnostic Value of Duodenal Drainage and Cholecystography in Gall Bladder Disease

Based on a Study of 137 Operatively Proved Cases

By

LAWRENCE J. RIGNEY, M.D.

WILMINGTON, DELAWARE

W. L. MORTENSEN, M.D.

SANTA MONICA, CALIFORNIA

and

T. GRIER MILLER, M.D.

PHILADELPHIA, PENNSYLVANIA

THE importance of the recognition or elimination of gall bladder disease in every patient with digestive symptoms is indicated by the fact that in this clinic 30 per cent of such patients eventually are diagnosed as having cholecystitis with or without stone. The development of duodenal drainage and of cholecystography seemed at first to supply a final solution to the diagnostic problem, but, in spite of many encouraging reports on those procedures, clinicians generally still question their value. This, as we shall show, is justified in a strict sense for either test alone, but at the same time our observations on a small group of operatively proved cases indicate that the two procedures, taken together, rarely fail to be of diagnostic aid when the gall bladder is diseased: we are not at this time considering their diagnostic value in cases that have no gall bladder pathology.

In each of 137 cases one or more satisfactory duodenal drainages and one or more (often three or four) reliable cholecystographic investigations were secured before operation. When any question as to function by either test arose we were inclined to record it as good rather than as poor or impaired. When the gall bladders were removed, as 120 of them were, they were subjected to careful microscopic as well as

those with stone (100 cases) and those without stone but with evidence of some gall bladder pathology (37 cases). We shall discuss these groups separately, and, in addition, we shall refer incidentally to a third group, made up of cases from the first two, those having gall bladders of the "strawberry" type (12 cases).

AGE AND SEX INCIDENCE

The age and sex incidence resembles that of other authors and is shown in Table I.

HISTORY

The history was regarded as suggestive of gall bladder disease when the patient had had repeated but irregular attacks of right upper abdominal pain, with or without jaundice, or a long story of indigestion that was not obviously indicative of other abdominal pathology. It was positive in 87 per cent of the stone cases, 76 per cent of the no-stone cases and 75 per cent of the "strawberry" cases. In the remaining cases the diagnosis was made and operation advised solely on the basis of objective observations.

PHYSICAL EXAMINATION

The physical examination was looked upon as positive when it revealed tenderness, with or without a mass, under the right costal margin. It was positive in 61 per cent of the stone cases, 54 per cent of the no-stone cases and 66 per cent of the "strawberry" cases. The highest percentage in the "strawberry" cases is worthy of note.

CHOLECYSTOGRAPHY AND DRAINAGE

All of the cholecystographic examinations were made after the oral administration of tetraethylthalein, some of the patients being given the dye after dinner on the preceding evening only, others after both luncheon and dinner of the previous day. Films were made on an empty stomach early in the morning; two hours later, just before giving a fatty meal, and a half hour after the fatty meal. The independent opinion of our roentgenologist, E. P. Pendergrass, was accepted as to the concentrating ability of the gall bladder and as to the presence or absence of shadows indicative of stone.

Biliary drainage was performed in the early morning by the usual technique, except that both magnesium sulphate and olive oil were employed for stimulation of the gall bladder. We often found that when

TABLE I

The age and sex incidence of 137 operatively proved gall bladder cases

Age	Stone Cases		No-Stone Cases		Strawberry Type	
	Male	Female	Male	Female	Male	Female
20 - 30		10		3		1
30 - 40	5	26	1	9		2
40 - 50	3	55	5	10	1	3

	15	55	9	25	3	9

gross examination. The cases were unselected except that those having unsatisfactory preliminary study were eliminated. They fell into two main groups:

From the Gastro-Intestinal Section of the Medical Clinic, University of Pennsylvania Hospital.

the magnesium preparation was not effective a subsequent instillation of olive oil led to the evacuation of dark colored, concentrated bile.

In analyzing the data obtained by these two procedures it is necessary to distinguish clearly between the observations that have to do with gall bladder function and those that bear on the presence or absence of gall stones. In the roentgenological study, function was judged on the basis of the intensity of the gall bladder shadow; stones, on the presence or absence of negative shadows or on the presence of positive shadows without dye administration. In the drainage test, function was determined by the character of the bile obtained after stimulation (whether or not the so-called "B" fraction was obtained); stone, by the presence or absence in the drainage material of cholesterol or of cholesterol and calcium bilirubinate crystals.

Four diagnostic possibilities as to the condition of the gall bladder, on the basis of these tests, present themselves: (1) normal function and no stones, (2) impaired function and no stones, (3) normal function and stones, (4) impaired function and stones. Ideally one should be able, on the basis of either of the tests, to fit each case into one of these groups. That such a diagnostic classification is impractical in many instances, however, is indicated by the following discussion of our data.

Obviously when both roentgenological investigation and duodenal drainage show normal function and no evidence of stone one is inclined to eliminate gall bladder disease. As we shall show, however, operation may in such cases disclose some cholecystopathy: in these the diagnosis, if made preoperatively, rests chiefly on the basis of the history and the physical signs.

Impaired function as indicated by the two methods of study may be compared. Reference to Table 2 and Chart 1 shows that cholecystographic investigation revealed impaired function in 60 per cent of our stone cases, in 38 per cent of the no-stone cases and in 58 per cent of the "strawberry" cases. These results resembled, but were not identical with, the observations on a lack of "B" bile by drainage, which occurred in 50 per cent of the stone cases, 46 per cent of the no-stone cases and 66 per cent of the "strawberry" cases. The discrepancies will be referred to later.

Whether or not stones are present with the impaired function can not always be determined preoperatively. Thus when the gall bladder function is markedly im-

paired or the cystic duct is blocked, one does not get, on roentgenological investigation, sufficient dye concentration in the gall bladder to show negative stone shadows (indicative of stones composed largely of

TABLE II
Diagnostic significance of various observations in total group of 137 cases

Observations	Stone cases (100) per cent	No-stone cases (37) per cent	Strawberry cases (12) per cent
History suggestive	87	76	75
Physical signs suggestive	61	54	66
Cholecystography: (a) stone shadows	42	13	17
(b) lack of function	60	38	58
(c) stone shadows or lack of function	89	51	66
Duodenal drainage: (a) cholesterol crystals	50	16	33
(b) lack of function	50	46	66
(c) cholesterol crystals or lack of function	90	59	91
Duodenal drainage or cholecystography suggestive of some disease process	100	62*	100

*Includes cases showing only calcium bilirubinate in the drainage material.

cholesterin) or, on drainage, material from the gall bladder in which to search for crystals. Since these conditions are frequently present one cannot expect, by either method, to make, in a large percentage of the calculus cases, a positive diagnosis of stone. Stone shadows by roentgenography, however, were found in 42 per cent of our stone cases and, to our surprise, in 13 per cent of the no-stone cases. The drainage results indicated stones (cholesterol crystals) in an even larger percentage of the stone cases (50 per cent), and in 16 per cent of those without stone. In most of those positive for stone by the roentgen ray and by drainage, therefore, function was not completely absent.

In estimating the total incidence of gall bladder disease, as indicated by these tests, it is necessary, therefore, to include all the cases that show either impaired

Chart 1. Percentage distribution of diagnostic observations on 137 cases of proved gall bladder disease (from Table II).

function or evidence of stone. Some show both; some, one or the other. On this basis 89 per cent of our stone cases showed gall bladder disease by roentgenography and 90 per cent by biliary drainage; of the no-stone cases, 51 per cent by cholecystography, 59 per cent by biliary drainage. The latter figure is increased if calcium bilirubinate alone is considered indicative of disease.

Kirklín (1) states that in his series of 415 operative proved cholelithiasis cases 99 per cent yielded positive cholecystographic data and that 70.8 per cent were diagnosed as having stones. He does not state specifically, however, that negative stone shadows were found in the 70.8 per cent; that hardly seems possible in view of the large number of our cases that showed no concentration of the dye in the gall bladder. Some of his cases, however, like some of ours, may have had positive shadows. Palmer's (2) data on a group of 131 stone cases are more consistent with our own: he found either stone shadows or non-visualization of the gall bladder in 94.7 per cent, and since 71 of his cases showed non-visualization it may be calculated that only 60 (46 per cent) showed stone shadows. On the other hand, Bockus, Shay, Willard and Pessel (3), in a series of 148 proved cases of cholelithiasis, found a positive stone diagnosis suggested by cholecystography in only 29.2 per cent, whereas it was suggested by drainage in 83.2 per cent; as suggestive of gall bladder dysfunction or disease, they found cholecystography helpful in 88.4 per cent, drainage in 98 per cent.

(d)	± in 2 0 in 5	absent in 5 impaired in 1	0	good	5	2
(e)	0	good	0	good	0	3

*"B" represents calcium bilirubinate, "C", cholesterol.

Stones were found at operation in 8 of our cases that showed crystals in the drainage material but, on roentgen examination, good gall bladder concentration, prompt emptying after a fatty meal and no stone shadows (Table 3 (a)). In 3 of them, however, only calcium bilirubinate pigment was recovered; in 4, cholesterol crystals alone, and in 1, both cholesterol and calcium bilirubinate crystals. The physical examination was positive in six of the eight cases. The history indicated the diagnosis in every instance. In this group absent stone shadows by the roentgen ray could have been due to such an increase in the density of the gall bladder shadow as to obscure the stones or

to so much calcium in the stones that they could not cast negative shadows: these observations indicate, as Rafsky (4) has claimed, that in some instances, in which the gall bladder retains its concentrating power and no negative shadows can be visualized by the roentgen ray, microscopy of the duodenal contents alone may indicate the diagnosis.

On the other hand, it would be surprising if one did not in an occasional case find crystals, even cholesterol crystals, in a patient with gall bladder disease who had not as yet formed a stone. Such crystals must begin to be precipitated at some time before a cholesterol stone is actually formed. In one of our no-stone cases that had showed crystals we searched diligently over the wall of the gall bladder and finally found a few very minute crystalline masses that proved under the microscope to be cholesterol in nature. This point deserves emphasis because Shay and Riegel (5) have claimed that the discovery of cholesterol crystals in the drainage material is pathognomonic of stone. Cholesterol crystals were found in 4 of our no-stone cases and curiously in all of them the roentgenological examination also suggested stones (Table 3 (b)). Eight of the no-stone cases showed calcium bilirubinate crystals, while but one of these was diagnosed cholelithiasis by the roentgen ray. Bockus, Shay, Willard and Pessel (3), in 1931, and Shay and Riegel (5), in 1936, stated that the discovery of both cholesterol and calcium bilirubinate crystals in the drainage material is pathognomonic of cholelithiasis, yet of our 37 no-stone cases 2 showed both varieties of crystals.

In search of an explanation of the roentgen diagnosis of stone in our no-stone cases we resubmitted to our roentgenologist the films of our 5 no-stone cases in which a roentgen diagnosis of calculus had been made, without his knowledge at the time of the operative findings or of our reason for so-doing, and in all but one of them he then expressed doubt as to the presence of stones, stating that the shadows might be due to gas in the colon. In only one instance, therefore, was an unequivocal roentgenological diagnosis of stone made in our 37 no-stone cases. It seems probable that less experienced roentgenologists frequently make the error of misinterpreting questionable shadows, and for this reason particularly the original diagnosis in our five cases is here recorded. In the one case no explanation for the negative shadow could be assigned.

Four no-stone cases and one stone case were able to concentrate the dye satisfactorily and also showed no crystals in the drainage material, but did show a lack of "B" bile (Table 3 (e)). These would have been accepted as normal cases except for the impairment of function, indicated only by the drainage test, and the facts that in all of them the histories were positive and in four tenderness under the right costal margin was demonstrable; in one, a mass was palpable. Operation revealed pericholecystic adhesions in all four of them, two having gall bladders of the "strawberry" type. These observations clearly indicate the importance of a detailed history and a careful physical examination in all instances and the significance of a variation from normal in any single laboratory result.

Pathology of the gall bladder as indicated by cholecystography, in the presence of completely negative drainage observations, was found only 7 times (Table 3 (d)). In 5 of these the gall bladder was not visualized; in 1, the concentration was slight but nega-

tive stone shadows were demonstrated; in the final 1, positive stone shadows were observed. Stones were found at operation in 5 of these patients.

It is appreciated that a failure of visualization of the gall bladder does not necessarily indicate a functionless gall bladder or a blocked cystic duct; it may be due to faulty excretion of the dye by the liver or, as Lake (6) has shown, to premature emptying of the gall bladder as a result of some disturbance in the action of the sphincter of Oddi. In spite of this, unless the liver is obviously diseased, we have felt justified in accepting a failure of visualization, under controlled circumstances, as evidence of gall bladder disease or of cystic duct obstruction. This proved correct in all of the cases covered in this report.

Both tests were entirely negative in only 3 instances (Table 3 (e)). In each of these dense pericholecystic adhesions to neighboring organs was the outstanding lesion. The history and physical examination were significant in all of them. Gall bladder adhesions may be the only evidence of pathology found at operation and, as Crohn (7) has stated, they may give rise to symptoms suggesting stones.

The "strawberry" gall bladder group is small (12 cases) but it will be observed (Table 2) that the concentrating power, as determined by each test, was more often impaired in this than in the no-stone group, that cholesterol crystals were present in only 33 per cent of the cases and that stone shadows were described in 17 per cent (stones present in 8 per cent). Although cholesterol crystals have been described as occurring frequently in cases of cholesterosis it will be noted that their incidence in our series was small: it was no greater than the presence of calcium bilirubinate. The mottled granular character of the mucosa

in one of our cases probably could have caused the shadows which were erroneously interpreted as due to stones.

CONCLUSIONS

1. In the diagnosis of gall bladder disease the history and the physical signs are of great importance and may occasionally justify operative therapy even in the presence of negative roentgenological and biliary drainage tests.

2. A positive diagnosis of stone in the gall bladder can be made on the basis of negative shadows by cholecystography or of cholesterol crystals in biliary drainage material in not more than half of the cases.

3. By means of either of these tests a diagnosis of gall bladder disease can be made in approximately 90 per cent of the cases with stone and in 50 to 60 of the cases without stone; but a strict diagnostic classification on the basis of the presence or absence of stone is frequently impossible.

4. Both tests should be employed routinely in suspected chronic gall bladder disease as a check on the information obtained from the history and the physical examination. In some instances one and in some, the other test will give important diagnostic aid; together they failed to be of help in only three cases of this series.

Glucose Tolerance in Anacidity

By

HARRY SHAY, M.D., J. GERSHON-COHEN, M.D., D.Sc. (Med.)

and

SAMUEL S. FELS, I.L.D.

PHILADELPHIA, PENNSYLVANIA

UNTIL recent years, gastric anacidity was generally believed to indicate disease of clinical importance even though the patient at the moment presented no serious symptoms. Latterly, however, the tendency has arisen to regard achlorhydria as an interesting but scarcely serious medical curiosity. This view is supported largely by the studies of Bloomfield and Pollard (1). In the general summary of their recent monograph on gastric anacidity they conclude that the lack of acid is, as a rule, an involutional phenomenon of no special clinical significance.

Our own observations do not support such an opinion. With Alvarez (2) we, too, have been impres-

sioned with the fact that the parietal cells of the stomach secrete hydrogen ions in a concentration a million times greater than that in the blood. One cannot accept categorically that nature should have singled out the stomach to produce a purposeless acid secretion. And then further to choose the mineral acid which ionizes most completely. Aside from any philosophical consideration of these facts, there is considerable evidence to show that the hydrochloric acid is concerned in many physiological processes other than its action in the stomach (3). The assumption is that these rôles for the hydrochloric acid find adequate compensation in anacidity, if no damage is to result. We believe from our studies that such compensation is often inadequate in the anacid patient.

A large literature on the effect of histamine upon

From the Samuel S. Fels Research Fund and the Gastro-Intestinal Division of Medical Service I, Mt. Sinai Hospital, Philadelphia, Pa. Read before the Section of Medicine, College of Physicians, March 22, 1937.

gastric secretion in relation to anacidity has accumulated, yet it has done nothing to explain the mechanism of anacidity, nor has it presented anything tangible to establish or deny its significance. Our own feeling is that the approach to the problem of anacidity has been much like the earlier approach to medicine generally.

Chart 1

That is, it has represented essentially a pathological rather than a physiological approach. A search has been made for palpable disease such as carcinoma and pernicious anemia in relation to anacidity, rather than for the more subtle physiological changes. We have stated recently (3) that anacidity may represent a change which has insidious and far reaching effects upon the body economy. We suggest even that some of the changes which we now accept as natural involutional phenomena incident to advancing years may find a contributory factor in the increasing incidence of anacidity that accompanies these later decades. Vanzant, Alvarez, Dustermer, Dunn and Berkson (4), in their splendid studies on gastric secretion were of a similar mind because they observed a falling off in the frequency of anacidity after the sixth decade. They suggest that possibly "The persons with achlorhydria are not so hardy or long-lived as are those who have a strongly acid gastric juice."

By utilizing a method previously described (5) in studying the motor function of the stomach and pylorus, we (6) were able to show that there is present in the human duodenum a mechanism which when activated appears to stimulate the pancreas in the production of insulin, and helps in the prevention of alimentary hyperglycemia. In these studies we found that the absorption of amounts of glucose that would ordinarily produce very definite increases in the blood sugar concentration, failed to raise the blood sugar level when duodenal stimulation was applied simulta-

neously. In these studies as well as in our previous investigation of the motor function of the stomach and pylorus, we were led to believe that the gastric hydrochloric acid served as the intrinsic agent which supplied the duodenal stimulus.

Chart 1, illustrates the effect of the duodenal instillation of hydrochloric acid in the prevention of alimentary hyperglycemia. In a normal person, after an overnight fast, the stomach was intubated and venous blood was taken for blood sugar. Two hundred and twenty-five cc. of 38.4% glucose were then given by mouth. Venous blood was again collected at 15 and 30 minute intervals after the ingestion of the glucose. At the half hour interval the stomach contents were removed, the stomach lavaged with three 200 cc portions of water, and the total glucose remaining in the stomach was determined. It was found that 25.5 grams of glucose had left the stomach either by absorption, through the pylorus, or both. Curve A, shows the change in the blood sugar levels that resulted.

On another day the duodenum was intubated, fasting venous blood was collected and 20 grams of glucose in isotonic solution were instilled into the duodenum, and blood again taken at the 15 minute and 30 minute intervals. The result is shown in curve B.

Curve C shows the result following the ingestion of 225 cc. of 41.5% glucose and the simultaneous duodenal instillation of 0.47% HCl at the rate of 100 drops per minute. Special precautions were taken as described previously (6) to assure ourselves that none of the gastric contents left through the pylorus. We were thus able to show that at the end of 30 minutes 20.6 grams of glucose had been absorbed, yet in spite of such absorption no rise of the blood sugar occurred.

From our own experiments (6) we felt justified in assuming that the hydrochloric acid in the duodenum called forth an agent which helped in the prevention of alimentary hyperglycemia. Such an opinion is not

Chart 2

without support. Thus Freud and Saadi-Nazim (7) found a drop in blood sugar in dogs following the duodenal injection of 60 to 100 cc. of 0.5% hydrochloric acid. This was confirmed by La Barre and Ledrut (8), and Gley and Hazard (9) demonstrated that the duo-

TABLE I

denal injection of hydrochloric acid was followed in the circulating blood of the animal by a substance which could lower the blood sugar. Sugar reducing effects from hydrochloric acid were reported in human beings by Coelho and Oliveira (10), Boatini (11), and Conti (12). Elsewhere (6) we have shown that this mechanism in man operates largely through pancreatic islet stimulation. We wish to emphasize too, as we have done previously, that the duodenal effect is not called forth solely by hydrochloric acid, but that the gastric acid serves as the intrinsic activator of the mechanism.

Chart 2 illustrates the results when olive oil or hypertonic solutions of NaCl or Na HCO₃ were substituted for the HCl as the duodenal stimulant.

From these observations we were prompted to consider whether the anacid patient, in whom this intrinsic factor is lacking, would show a greater tendency to disturbed carbohydrate metabolism than would a similar control group of patients with normal or hyperacidity.

This report is based upon the study of the three hour glucose tolerance curve in fifty anacid patients and in a similar control group of patients with normal and hyperacidity. The objective studies on the anacid patients were done on an entirely unselected group. None of these patients clinically suggested any disturbance of carbohydrate metabolism. In all a routine blood sugar was within normal limits. None showed any evidence of neoplastic gastric changes. The test load consisted of 100 grams of glucose plus the juice of one lemon dissolved in water so that the total volume was 250 c.c. The test was done in the morning following an overnight fast. After taking venous blood for a fasting blood sugar, the glucose was administered and venous blood taken at 30, 60, 120 and 180 minutes thereafter. Blood sugar was determined by the Folin-Wu method.

In view of the increasing incidence of anacidity and abnormal glucose tolerance curves in the higher decades, selection of the control group was made from patients corresponding in age periods to those in the

Glucose Tolerance Curve in Control Group of Fifty
Normal and Hyperacid Patients.

TABLE II

anacid group. The ages ranged from 29 years to 54 years, with approximately the same number of cases in each decade in both groups.

RESULTS AND DISCUSSION

Since there is no unanimity of opinion on the criteria that establish the normality of a glucose tolerance curve, we have classified our results so as to grade the response according to the changes which are considered abnormal. Thus we have recorded as negative those curves which start with a fasting blood sugar below 120 mgms. per 100 c.c., reach a peak after the 100 grams of glucose of less than 180 mgms., and return at 120 and 180 minutes to levels below 120 mgms. As plus 1, we have included curves which start with a normal fasting level, reach a peak above 180 mgms. per 100 c.c. of blood, and drop below 120 mgms. at 120 and 180 minutes. Under plus 2, we have placed results which reached a peak above 180 mgms., remained above 120 mgms. at 120 minutes but dropped below 120 mgms. at 180 minutes. Included also as plus 2 curves

were those which showed a two hour reading above 120 mgms., although the peak did not exceed 180 mgms. We did so, because we believe that a prolonged curve is indicative of a greater disturbance in carbohydrate utilization than is a high peaked curve. Finally, in the severest grade of plus 3 were included those curves which in addition to the abnormal peak, were still above 120 mgms. at 120 and 180 minutes (Table III). Tables I and II show the results obtained in the two groups of people. In Table I, the anacid group shows an unusually high incidence of abnormal glucose tolerance curves as compared to the control series of normal and hyperacid patients in Table II. Appreciating that at times glucose tolerance tests may yield abnormal figures which are not confirmed when the test is repeated, we did a second tolerance test a week later on all cases which yielded a positive result. Those which failed to yield a second positive result were not included in this series. In the anacid group abnormal curves of one degree or another were found in twenty-four of the patients, an incidence of 48%. Of these,

two fell into our classification of plus 1, fourteen as plus 2, and eight as plus 3. In the control group only eight showed curves that deviated from the perfectly normal response. Of these five belonged to plus 1 group, two, to plus 2, and one, to plus 3, (Table IV).

TABLE III

	Peak (mgm. per 100 c.c.)	120 min. (mgm. per 100 c.c.)	180 min. (mgm. per 100 c.c.)
Normal	<150	<120	<120
Plus 1	>150	<120	<120
Plus 2	>150 >150	>120 >120	>120 >120
Plus 3	>150	>120	>120

It is interesting to note the difference in grouping of the abnormal sugar curves in the acid and non-acid groups. We see in the anacid group not only a higher incidence of abnormal curves but a distinct tendency for a greater deviation from the normal.

Does the high incidence of abnormal tolerance curves in the anacid group represent a large percentage of mild and potential diabetics, or does it merely represent evidence of a disturbed duodenal mechanism because of the anacidity? Our own studies make us feel that anacidity is probably not infrequently a determining factor in the production of abnormal tolerance curves. Such an opinion is fortified by the changes in the glucose tolerance, in different age groups, noted by some observers. From the splendid studies of Vanzant, Alvarez, Eusterman, Dunn and Berkson (4), of Keefer and Bloomfield (13), of Dedichen (14), and of Davies and James (15), the relation of increasing age to a rising incidence of anacidity has been clearly shown. It is probably, then, more than coincidence that a diminishing sugar tolerance should be met with under similar circumstances. Thus John (16) found the glucose tolerance curve normal in 82% of children

but only 62% of adults. Similar results were reported by Spence (17). Hale-White and Payne (18) concluded that the sugar tolerance curve in old age showed a higher rise and a slower fall than the usually accepted standards and Marshall (19) obtained curves typical

TABLE IV

of mild diabetes in 14% of healthy old persons, although none of them showed any symptoms of diabetes.

SUMMARY

Fifty anacid and fifty patients with normal and hyperacidity were studied with the three hour glucose tolerance test. After the ingestion of 100 grams of glucose, a surprisingly high incidence of abnormal curves was found in the anacid group. Forty-eight per cent of the anacid patients showed an abnormal glucose tolerance curve, while only 16 per cent of the control group showed such a disturbance.

The concern of normal duodenal activity with the presence of gastric hydrochloric acid and the relationship of that activity to the prevention of alimentary hyperglycemia are suggested as the mechanisms whose disturbance in anacidity may be responsible for the differences observed between the two groups. The higher incidence of abnormal glucose tolerance curves in advancing years is believed to be related to the higher incidence of anacidity in those age periods. It is our belief that anacidity represents not only a loss of gastric function but also is of real clinical significance in conditioning disturbed physiological states in parts of the body often quite remote from the stomach.

Laxatives and Bowel Consciousness—A Clinical Study*

By

MANFRED KRAEMER, M.D., F.A.C.P.†

THE unrestricted and indiscriminate sale and use of laxatives has resulted in purgative addiction by a large proportion of the American public. In order to obtain some facts in regard to the prevalent use of cathartics and the relation of constipation to the use of laxative drugs, a detailed laxative history was taken, along with the history of bowel habits in a series of 300 consecutive patients in private practice. Similar histories were taken on a number of patients at the gastro-intestinal clinics of the Newark Presbyterian and the Flower-Fifth Avenue hospitals. In view of the difficulty in obtaining accurate stories from clinic patients, the figures obtained from them are not reported. Their habits parallel those of the private group.

Nothing in this paper must be construed to refer to constipation due to organic obstruction (stricture or tumor), or constipation resulting from spinal cord disease.

Early in this study we ceased to regard constipation as a disease entity and dropped the differentiation between spastic, atonic, and rectal types as not worth considering either from the point of view of etiology or treatment. We have concluded that constipation as a disease entity does not exist; that constipation is a symptom arising in a person's mind. Every patient had a different conception of constipation. The use of laxatives is evidence of bowel consciousness, not of constipation.

This study represents a fair cross section of the public (Table I). 61 different diseases were represented. Of the 300 patients studied, 161 were males and 139 females. Table II shows the number in each age group. Only 2 patients declared that they had never taken a physic. Of the 300 cases, 36 females and 43 males took laxatives less frequently than 4 times a year (Table III). These 79 patients were excluded from the statistics regarding habit formation, for patients taking physics less often than once in 3 months can scarcely be considered bowel conscious. The incidence, therefore, of laxative addiction for the entire group was 73%. The proportion in males and females was exactly the same. This is in contradiction of the general opinion that more women take laxatives than men. Since laxative addiction and bowel consciousness go hand-in-hand, we can conclude that over 70% of our patients are sufficiently bowel conscious to take a laxative more frequently than once every 3 months. Further, in regard to the frequency of taking laxatives (Table III): of the 300 patients, 71 or 23% took laxatives daily. 161 patients or 53% of the whole group took laxatives weekly or more often.

We thought it of interest to determine how many

Total: 300.

different laxatives were taken regularly (Table IV). 95 or 43% of the group took only one type or brand of laxative. 72 or 32% took two brands of laxatives regularly, and two of the group took more than 8 different laxatives. A frequent reply to the question, "How many laxatives do you take?" is, "I take every thing I hear of."

While the common age of onset of the laxative habit for both males and females was between the ages of 20 and 30 (Table V), there is a greater disposition on the part of girls than of boys to form the habit under 20. This is probably due to the misconception that proper menstrual activity can persist only if associated with a daily copious bowel excretion.

As to the years of duration of the laxative habit (Table VI): 112 of the patients had been addicted for

*From the Newark Presbyterian Hospital and the Department of Gastro-Enterology of the New York Medical College and Flower Hospital.

less than five years, but 108 had been taking laxatives from 6 to over 40 years. There was no significant sex variation in the duration of the habit.

Table VII shows the various reasons given by patients for taking laxatives. The most frequent

traced the origin of their laxative habit to their parents. Mothers often insist that the children take a physic once a week, "to get a good cleaning out."

answer to the question, "Why do you take laxatives?" was, "my bowels can't move without one," and the next most frequent answer was, "When I get a pain in my stomach." Curiously enough 6 patients took laxatives for diarrhea and 9, merely because they thought, "they were good for you," and 2 on "general principles."

A study of the various laxatives taken (Table VIII) revealed that cleansing enemas were the most popular, with mineral oil a close second. Enemas were not popular with those who took laxatives frequently, and were rarely the only laxative taken. In enumerating the laxatives taken, the patient would usually conclude, "and occasionally, an enema." No differentiation was made between enemas and so called "high colonics." Those taking laxatives on a physician's order, usually took mineral oil or milk of magnesia.

The main purpose in studying these patients was to determine on whom to place the blame for the creation of bowel consciousness. Four groups are directly responsible: advertisers of laxatives, the medical profession, parents and friends. In the last group are included husband or wife. It is difficult to accurately determine how much the other three groups are influenced by advertising. We tried as best we could in each case to place the blame where it belonged. The advertisers (Table IX) were responsible as often as the other three groups combined. 21 of our patients

Several patients have told a similar story: "On Saturday night after our bath we were all lined up and given a tablespoonful of castor oil."

A second instance where parents can be blamed for starting the laxative curse is during puberty. At this time many girls look below par for reasons we cannot now go into. Mother asks, "Did your bowels move today?", and if the answer is "no" or "only a little," mother replies, "Oh my, you're going to have the same troubles I had. I had the same difficulty and had to take physics and have been forced to take them every other day for twenty years since." Mother then prescribes her favorite physic and daughter becomes bowel conscious and the laxative habit is started.

Many other examples might be quoted regarding the establishment of bowel consciousness and laxative habits by parents. In the presence of common colds, grippe, acute "stomach upset," or gastro-enteritis, the parents first impulse is to administer a purge. Not only is this "cleaning out" followed by constipation for which the child will often take another cathartic in a few days, but it also associates some malific influence in the child's mind between the fecal contents and these diseases. It is well known, that colds, grippe, and acute gastro-intestinal disturbances are self-limiting and that cathartics are of no particular benefit.

A contributing cause of America's bowel conscious-

ness is the attitude of the medical profession. This attitude must be expressed from many angles. The physician not only frequently causes bowel consciousness on the part of the patient, but in the treatment of the average case of constipation he continues an

use of mineral oil or milk of magnesia post-operatively, and in many of our patients we have traced the onset of the laxative habit to this pernicious practice.

Physicians are markedly influenced toward the prescription of laxatives by the tremendous amount of

already well established habit. I confess that I have rarely if ever witnessed any organic change result from the use of laxatives and many may ask, "Why bother about the subject if laxatives never hurt anybody." My answer is, that as physicians we must not only cure organic disease, but must help our patients over mental difficulties. The life of the average cathartic habitue is often made miserable and is as lacking in happiness as that of many sufferers from chronic organic disease.

How do physicians initiate bowel consciousness? How often on approaching the sick bed, we first ask, "Did his bowels move today?" Immediately, both patient and family are made bowel conscious. Post-operatively does not the surgeon put on his most sober expression and interrogate the nurse, "Have the bowels moved yet?" Many surgeons recommend the routine

advertising which is directed at them. One month's accumulation of laxative advertising arriving by mail and clipped from Scientific Journals fills a legal sized folder. Try as he might the physician cannot escape the constant bombardment which draws his attention to "Habit Time," "Spastic Colitis," "The most prevalent ailment," and the superiority of "Miscibility," or "The physiological restoration of bowel rhythm."

In several instances in our series, in those cases listed as originating through the physician, we have obtained the following type story. "After my operation I had trouble with my bowels and until I left the hospital, I received an enema every day. When I arrived home my bowels did not move for two days, so I called the surgeon and he told me to take some magnesia. Later, when I went to his office he told me to take Petrolagar every night, and I have been taking it ever since." Unwittingly, the well meaning surgeon has started a pernicious habit.

The converse to what I stated previously is also true, while I have never known a cathartic to produce

serious organic change, I have never found the retention of feces for five or six days to result in any further hardship than a mild headache, a sense of fullness or a difficult passage.

The obstetricians are often the responsible party in the production of bowel consciousness. On the direc-

TABLE IX

Total	221

tions issued to expectant mothers, the following statement often appears. "If the bowels do not move every day a mild laxative should be taken, either mineral oil, or milk of magnesia, or a low enema." How much better it would be to omit any mention of the bowels or to state, "If the bowels do not move for a day or two, do not become alarmed, they will eventually move of their own accord." It is routine on the part of many obstetricians to prescribe laxatives or enemas daily, post-partum. This practice had best be discontinued.

There is still another way in which we, as physicians, stimulate bowel consciousness and that is, in the treatment of constipation itself. Instead of belittling the patient's complaint, we take it seriously and prescribe measures to combat the "disease." This insistence on our parts to treat the condition, again is an instance of the provocation of the patient's imagination toward the association of retained feces and some dreadful scourge.

This paper does not touch on therapy, but as a

general rule the prescribing of cascara or bran or regulin or mineral oil preparations merely substitutes one laxative for another.

Lastly, we must touch on the influence of advertising on the establishment of bowel consciousness. 112 cases were traced directly to this source. The drug houses have taken advantage of the public's newly aroused health consciousness. Commercial success accrues to any manufacturer who can, by means of advertising create sufficient bowel consciousness in the public mind to sell a person only a few doses of his product. Since laxatives are usually habit forming, repeat orders pile up and a business is established.

Misbranding laxatives as candy and advertising to mothers to give regular doses of this or that purge assures not only one single sale, but continuous business even after the advertising stops. Some of our patients are taking "Liver Pills," and other proprietary preparations which have been advertised either to physicians or to the public for twenty or more years.

CONCLUSIONS

A program for the prevention of bowel consciousness on the part of the American public must be aimed at the source of this condition. First, parents must be educated against the use of laxatives and must be cautioned against over-emphasizing bowel function. Second, physicians must be more guarded in prescribing laxatives. They must show less concern regarding the functional activity of the colon. They must treat constipation by withdrawing laxatives and not by prescribing additional ones. Third, there must be a legal curb to the advertising of laxatives, in the press, and the radio, and by mail.

Imaginary diseases and symptoms are real to the patient. Patients' lives have been made miserable because of constant bowel consciousness and the constant use of laxatives. With 70% of our public addicted to laxation by drugs or enemas, it is high time that something be done about it.

The Treatment of the Individual in the Care of Peptic Ulcer^{*†}

By

JACOB MEYER, M.D.[‡]

and

J. KASANIN, M.D.[§]

CHICAGO, ILLINOIS

ALTHOUGH it is generally recognized that there is no specific medical treatment for peptic ulcer, the alkali management with a dietetic regime as suggested by Sippy is accepted as a standard form of therapy. Internists and surgeons at present agree that there are definite complications of peptic ulcer which require surgical treatment but that in any case of peptic ulcer, a long period of carefully supervised medical treatment should precede any form of surgery. The surgeons are primarily interested in the various types

of operations, and the controversy has largely been as to the respective merits of gastro-enterostomy and gastric resection.

It is our purpose in this communication to emphasize the importance of the treatment of the individual as a whole. In addition to any accepted form of ulcer therapy, we feel it important to treat the individual as well as the ulcer. The treatment of the individual is not advocated as a specific method for the therapy of peptic ulcer, but follows the same principle as in other fields of medicine. However, it is our impression that such treatment has its greatest field in the domain of gastro-enterology.

Numerous observers have called attention to the

^{*}From the Stomach Study Group and the Department of Psychiatry, Michael Reese Hospital, Chicago, Illinois.

[†]Read at the Chicago Society of Internal Medicine, February 22, 1937.

[‡]Attending Physician—Michael Reese Hospital, Chicago, Illinois.

[§]Attending Psychiatrist—Michael Reese Hospital, Chicago, Illinois.

importance of the personality in the etiology of ulcer. While we have recognized the importance of emotion, with tension and anxiety as factors in the etiology of ulcer, very little has been said regarding their role in the therapy. As a simple illustration of our thesis, it is known that a great many patients will be relieved of the symptoms of ulcer by a change of environment, by rest, or by simple modification of the diet, without medication. This relief or amelioration of symptoms has been interpreted either as a spontaneous abatement of symptoms, healing of the ulcer, or as something unexplainable. We suggest that combined medical and psychiatric study may explain such instances.

In approaching our problem it is essential first, to make a correct diagnosis of peptic ulcer. It is most important to differentiate between a functional syndrome of ulcer and a clinical picture due to an organic lesion in the stomach or duodenum. A good clinical history is the first essential in diagnosis. The experienced clinician readily appreciates the variability of the symptoms in the nervous dyspeptic and will easily exclude a functional disease. Ordinarily, in addition to the history we rely on direct X-ray evidence of ulcer, the presence of blood in the stomach contents and in the stools. In cases where all these laboratory findings are definite, the problem of diagnosis is not difficult. In the early cases of ulcer, the history may be typical but the X-ray examination may be indefinite and the laboratory evidence inconclusive. In such instances, the diagnosis depends on the evaluation of the individual; and every well-trained physician should be able to accomplish this. The psychiatrist has developed a technique of study of the individual which serves to elucidate functional factors. However, in the majority of instances, the general practitioner or the specialist may accomplish the same result because of his intimate knowledge of his patient, the patient's family environment and social background. There are, of course, some cases which definitely call for a more specialized psychological investigation, necessitating a psychiatrist.

In the course of history taking and of medical observation, a patient unfolds his problems to the extent to which the physician has established the confidence of the patient. The faculty of listening to the trials and tribulations of a business man or the disappointments of a love affair may not only serve to make a correct diagnosis, but tends to further therapeutics.

The general practitioner has often employed the verbal catharsis of the psychoanalyst without being aware that he was using a specialized technique, and this art has been lost by the specialist.

Internists and gastro-enterologists have always emphasized the greater importance of a history properly taken and evaluated, in the diagnosis of peptic ulcer, than any other clinical or laboratory test. We re-emphasize this point and add that in this history, the role of the individual as a whole be considered in relation to the symptomatology.

At the Mandel Clinic, Michael Reese Hospital, we have conducted our examinations of peptic ulcer patients in the form of a conference, the internist, the psychiatrist, the physiologist, the surgeon, and the social worker participating.

The social composition of our patients is much as in other clinics. All our patients are white, the propor-

tion of men to women is about twenty to one. Racially, sixty per cent of our patients are of Anglo-Saxon stock, and about forty per cent are Jews.

The routine procedure has been for the internist to take a careful history and make a complete examination. The history is supplemented by a complete report from the social service worker. An attempt is first made to make a clinical diagnosis on the basis of the history and the physical findings. In many instances the diagnosis is made before roentgen examination but in all cases, an X-ray is taken in the usual routine manner. The internist evaluates the clinical picture as a whole and then discusses the cases with the psychiatrist, the social worker, the physiologist, and the surgeon. Where the social problem is very prominent and can be treated by the Social Service Department, the physician will try to adjust his therapy to fit in with the social worker's program. When the emotional or psychogenic influences are the predominating factor, the psychiatrist will make a study of the patient and will make his recommendations, the patient remaining, however, under the observation of the internist.

Our experience with this approach has encouraged us a great deal. It becomes clear at once that a patient who is well adjusted socially has less concern about his symptoms than otherwise. The internist explains the nature of the ulcer symptoms to the patient. A simple routine of medical therapy for ulcer is instituted which consists of a soft diet, distributed in six feedings. Small doses of atropine may be added for a short period, and alkalies may or may not be administered. An explanation is given to the patient, also, of the importance of relaxation, the need of rest, vacations, and the relation of the emotional life to the symptomatology.

In studying the personality of the patient, one must begin with a thorough review of his major life reactions. It is a very good idea to get a general impression of the patient, especially in reference to his fundamental traits. Is the patient domineering, aggressive, restless individual, or is he an introverted, quiet, submissive, docile person? Has he been quite independent in his career as a member of society or has he always followed the lead of someone else? This is especially important as in quite a large number of our cases we found rather passive, submissive individuals, extremely dependent upon their mates, and yet revolting against them, as shown by a good deal of friction in their marital lives. In this connection, it is worth while to learn the sexual adjustment of such patients.

The industrial adjustment of such individuals is very interesting, especially from the point of view of their ability to hold a position during the medical treatment of ulcer and also following operation. This has been made the subject of a special study and will be reported later. (Meyer and Scher).

The patient's reaction to society and to his fellow-man is another important factor to which a good deal of attention must be paid. Very often the patient blames the difficult economic period, as well as his ulcer, as the cause of his industrial maladjustment. It is very difficult to determine whether the patient's maladjustment is due to his disease or to the particular economic stress to which he is being subjected. Clinicians have long recognized that a recurrence of symptoms can be associated with a severe emotional upset. In a great many instances it is possible to note

an amelioration of the symptomatology when the social-economic or sexual problem has been adjusted.

We wish to present now an outline of the various forms the therapist may employ depending on the nature of the case.

1. Hygienic Recducation.

With simple instructions in reference to rest, relaxation and divided food intake as suggested above.

REPORT OF A CASE

L. W., a young American, age 42, dress-salesman, bachelor, duodenal defect with deformity, duration 12 years, periodic recurrence despite treatment by various excellent clinicians. This patient had periodic recurrences each Spring and Fall, which were definitely associated with the tension of his business activities. With every season's change in style of dresses he was constantly returning to the same driving tension of a highly competitive and nerve-wracking business. His life was one constant rush from one city to another to obtain his orders, and it was then that his symptoms recurred. His bowel habits were bad and he constantly complained of constipation.

The first step in the patient's treatment was to explain the importance of a scheduled daily routine. The importance of relaxation in his business life and its relation to his symptomatology was made clear. A scheduled routine of diet was advised. Atropine, together with alkalis, was administered and the patient was asked to return for repeated observations. The patient was also asked to return especially at presensory periods—and also at periods of greatest emotional tension. This treatment gave very satisfactory clinical response. The symptoms abated, the retention diminished and the patient was able to continue at his occupation. He has had occasional recurrences, but these were mild in character. He is able to continue his work without interruption and sees the physician only when notified to do so.

2. Simple Suggestive Therapy.

When a patient is somewhat tense and anxious without any evidence of a clear-cut neurosis, simple suggestive therapy with medication is very much worthwhile and proves to be successful in a great many cases. One must remember that even atropine and alkalis have a very powerful suggestive effect, together with their specific value in ulcer therapy.

3. Therapy by Intellectual Insight.

In a good many cases the patient enjoys receiving a great deal of attention which naturally comes with any physical illness. This holds especially true in young, somewhat immature individuals with families who always have been over-protective, and in such cases there is a marked "secondary gain" from the illness. In these patients a review of the personality with explanation of some of the mechanisms of their behavior, results in gaining intellectual insight which helps them to change their attitude toward their illness and liberates them from a dependent position in the family.

4. Social Therapy.

As we have indicated, many of our cases may be caused by difficult social and environmental situations. In such cases proper environmental manipulation by the social worker, which gives the patient a sense of security in the unstable world which surrounds him, may lead to a marked improvement. In private

practice, where the agency of a social worker is not available, the physician must function in that capacity, as physicians always have functioned.

5. Therapy of a Dependent Attitude Upon Physician or Clinic.

There is a very important group of patients who are very faithful, and who come to the clinic time and again without showing any subjective improvement. Such patients become extremely dependent upon the clinic and especially upon the physician for whom they develop a deep emotional attachment. There is no question but that these patients have serious economic problems; but the more the physician tries to help them and understand them, the less improvement they show.

Case 2. A man of 46 has been coming to the clinic for a year and a half, complaining of epigastric distress recurring regularly after meals, associated at times with nausea and belching, relieved by intake of food and soda. Vomiting was present on occasions and severe night pain was particularly striking. Duration of symptomatology was approximately nine years. Both the patient and his wife were extremely proud people and it was only under considerable pressure that they consented to accept a certain amount of help. The patient was extremely touched by the physician's interest in him. On each consecutive visit he became more and more sentimental, shed copious tears, bemoaned his ill fortune and persisted in his gastro-intestinal complaints. An X-ray of the gastro-intestinal tract showed a duodenal deformity. Various types of medication were tried, without much relief. A study of the patient's background revealed the fact that the patient came from a stock where there was a great deal of admiration for religious learning. When the patient was a young man he became acquainted with the daughter of a distinguished clergyman who at that time came on a missionary tour to America. The patient was fascinated with the young woman and felt very happy when she consented to marry him. He became very ambitious and energetic and to prove his own worth he amassed a fair fortune. All this was lost in the depression, which was followed by a complete rejection of the patient by his wife. Hence, the extreme attachment to the physician, who in a sense, symbolized to the patient the same thing. The more the patient was helped, the more he wanted help and the less he improved. For this reason, a very drastic attitude was taken, with a complete change of attitude toward the patient. He was told that he must cease being a child, that he must go out and work, and face his responsibilities like a mature man. This was followed by a marked emotional display on the part of the patient and a rather quick adaptation to reality situations with marked diminution in symptomatology. Such radical treatment may be indicated in these types of cases.

6. Psychoanalysis: Patients with definite neurosis which can be helped only by intensive psychotherapy of a rather specialized kind, including psychoanalysis.

It is known that an ulcer may be symptomless. The general explanation has been that such ulcers occur in regions which may be termed "silent areas." Such ulcers may show symptoms only at the time of hemorrhage or perforation. Apart from the location of "silent areas," the absence of symptoms has been explained by the fact that their threshold for pain sensitivity is high. This probably is true, but it occurs to us that there are other factors which may serve to explain the absence of subjective symptoms. There are a number of ulcer patients who occasionally complain of distress, but it is either minimized by them or

does not register in their consciousness. When such patients become disturbed emotionally, or beset with special problems which they cannot meet, the symptoms of ulcer come to the foreground and it is then that they complain of their distress, and become aware of being ill. Hence the appearance of symptoms in emotional stress and conversely, the disappearance of symptoms when there is a favorable change in the total situation. This explains why simple removal from a difficult situation at home may help the patient without any medicinal therapy.

We doubt very much whether one can hope for a complete relief of symptoms of peptic ulcer in a maladjusted individual. In our experience, we have seen time and again, how even with the removal of pathology, patients remain ill and keep on returning to the Gastro-Intestinal Clinic, presenting new symptoms which are nothing but somatic conversions of their underlying emotional problems. This is also true of a patient with a healed duodenal ulcer and a social maladjustment.

The tendency of a peptic ulcer to heal spontaneously is well known. This is particularly true of gastric ulcer; and post-mortem studies reveal many healed ulcer scars. Duodenal ulcers likewise have a normal tendency to heal, irrespective of any form of therapy.

On the other hand, the treatment of ulcer by alkalies or any other form of medical management has its percentage of failure as well as its percentage of cure. Some of these failures may be definitely attributed to the complications of peptic ulcer, such as pyloric stenosis, penetration into the pancreas, perforation and hemorrhage, which require surgical intervention. There are, however, a percentage of failures following medical ulcer therapy of any type which we are unable to explain. The inability to explain or correct these failures has often resulted in needless operations, or patients have become cultists or confirmed neurotics. If we analyze these failures in the light of what we know of the individual, we may explain the origin of the symptoms and either with or without medicinal therapy obtain a favorable result. Thus our percentage of failures by medical therapy should be decreased.

Patients do have recurrences of symptoms, even if they are well-adjusted emotionally, and these recurrences may be due to activity in the ulcer itself. It is

equally true that patients have recurrent symptoms despite treatment by any accepted forms of ulcer therapy and these recurrences may also be associated due to activity in the ulcer. The reasons for the recurrences are apparently not always clear to us, despite all of our attempts at clinical or psychological explanation. Lest we be misunderstood, we wish to emphasize that the social adjustment or any other form of adjustment is advocated only as a great aid in stabilizing an individual patient and make him less vulnerable to recurrence of symptoms.

May we not assume that in adjusting our patients, we may alter secretion and motility in such a way as to have a favorable influence on the healing of a peptic ulcer. If we accept the role of emotional influences in the genesis of ulcer may we not accept the idea that the emotional adjustment may have a beneficial effect in the therapy?

SUMMARY

1. The importance of the individual as a whole, has not been considered sufficiently in the discussion of ulcer therapy.

2. In the normal individual who has a peptic ulcer, the stress and strain of emotional, business, social and sexual problems, interfere and aggravate the symptoms of the ulcer. If the physician can help the patient to solve some of his difficulties, such therapy is conducive to the healing of the peptic ulcer. We consider such treatment an important adjunct in the medical therapy of peptic ulcer.

3. Investigation of the emotional life of the patient is important in the differential diagnosis of peptic ulcer. It is particularly important in early and doubtful cases.

4. Since it is difficult at times to differentiate between a "healed ulcer" — with an ulcer syndrome due to an "emotional" state and an active ulcer with ulcer symptoms, an investigation of the emotional life of the individual is important for the therapy as well as diagnosis.

If patients have recurrent ulcer syndrome following apparently successful operations for ulcer, it is important to investigate the individual as a whole before attempting further medical or surgical therapy.

The Value of Cholesterol in Milk*

By

O. L. STRINGFIELD, M.D.:
NEW YORK, NEW YORK

AMONG the hundred or more recognized constituents of milk is the substance known as cholesterol. Chemically, it is a sterol with the formula, $C_{27}H_{46}O$. Quantitatively, it is one of the relatively minor components of milk, since this sterol is present in whole

milk only in amounts varying from 10 to 15 mg. per 100 c.c., or from 100 to 150 mg. of cholesterol to the quart of milk (1). There seems to be no evidence to show that cholesterol is more, or less, abundant in any particular grade or type of cow's milk. It also occurs in human milk.

Qualitatively, however, this small amount of cholesterol in milk is a matter of some significance, as indi-

Read at the meeting of the American Association of Medical Milk Commissioners, Atlantic City, N. J., June 8, 1937.

cated by the functions attributed to cholesterol in the human organism by Hurxthal and Hunt (2). These functions are ascribed as follows:

- "1. A constituent of the framework of cell because of its stability to ordinary chemical change.
- "2. A protective substance in cells, exerting its effect as:
An anti-toxic, anti-hemolytic and anti-infectious agent.
An insulator of the central nervous system.
A conditioning constituent of the skin.
- "3. A conveyor of fatty acids to and from fat deposits.
- "4. A facilitator of fat absorption."

Because of the importance of cholesterol in human metabolism and because milk is such a valuable adjunct to our diet, it seems desirable briefly to call attention to some of the more recent studies made with cholesterol showing its value in milk.

Although it has been asserted recently that a high cholesterol diet may be a factor in the development of human atherosclerosis (3), a form of arteriosclerosis characterized by degenerative changes in the connective tissue of the arterial walls, the evidence which tends to incriminate cholesterol as a cause of this condition is not impressive. Although abnormal deposits of cholesterol are consistently found in the atherosclerosis plaques, and the amount increases with the extent of the atherosclerosis, no one has as yet definitely proved that the deposition of cholesterol is the cause rather than the result of the disease. Cholesterol deposits are also found in the body in gall bladder disease, in uncontrolled diabetes, lipid nephrosis, and in a number of other morbid conditions. These deposits seem, however, to be the result of a disturbance of metabolism, and not the causative factor of the disease.

That this is so in the case of atherosclerosis is indicated by the work of Lande and Sperry (4), who compared the concentration of cholesterol in the blood serum with the lipid content of the intima of the aorta in 123 necropsy cases. They found no correlation whatever between these two factors, even in subjects with a marked degree of atherosclerosis, and reported that the average amounts of cholesterol in the serum of these persons were practically identical with those noted in normal healthy subjects.

These results, as well as other experiments, says an editorial in the *Journal of the American Medical Association* (5), "clearly indicate that factors other than the concentration of cholesterol in the blood must be involved as etiologic agents in the production of the lesions characteristic of this disease."

Atherosclerosis has been produced in the rabbit by Leary (3), by overwhelming the weak metabolic system of this animal with doses of crystalline cholesterol, but this fact does not have a human application. In the normal human body, cholesterol is both synthesized and destroyed, so that the bodily requirements for this substance are maintained in a state of equilibrium.

Although it has been alleged (3) that the use of high fat diets in the treatment of diabetes during the decade from 1920 to 1930 resulted in an increase of arteriosclerosis among these patients, no statistical

data have been adduced to support this contention. Freyberg, Newburgh and Murrill have shown, furthermore, that there is no correlation between the level of cholesterol in the blood of diabetic patients and the amount of fat in the diets (6). These investigators state that lack of control of the diabetes appears to be the major factor in the causation of hypercholesteremia in diabetic patients.

Although other sterols occur in plants, cholesterol and the related substance, ergosterol, are the only sterols found in the animal body, according to Bills (7), who has written a noteworthy review of the physiology of the sterols. Cholesterol is a constituent of body cells, being especially abundant in the brain, where it is thought to act as an insulating medium for the myelin sheaths of the nerve fibers. Cholesterol is usually associated with fat, forming esters with the fatty acids. It is present in the blood both in the form of cholesterol and as cholesterol esters, the normal range being considered to be from 120 to 230 mg. per 100 c.c. (2). Determination of blood cholesterol has a diagnostic value, although many factors may influence the quantity present.

In a recent article, Bills (8) states: "The fact that vitamin D is not a single chemical substance has only recently been recognized. The erroneous view still commonly held is that ergosterol is the parent substance, or provitamin, from which all vitamin D arises."

The irradiated ergosterol is the most thoroughly studied of the vitamin D group. Irradiation of yeast fed in proper amounts to cows produces a vitamin D in the milk, the provitamin of which is ergosterol. This is the vitamin D present in certified milk.

In the human skin, the fat is comprised of about 19 per cent cholesterol. The provitamin of cholesterol according to Bills (8) is 7-dehydro-cholesterol. Under the influence of ultraviolet light from the sun, or from artificial sources, this cholesterol is activated through its provitamin, becoming an active antirachitic agent. The provitamin in the cholesterol of milk, which is probably 7-dehydro-cholesterol (8), is changed into the antirachitic vitamin D, when subjected to irradiation. Ansbacher and Supplee (1) have shown that about 82 per cent of the cholesterol in milk is in the fat, and that the remaining 18 per cent is found largely in the milk protein, lactalbumin, with which the vitamin D produced in milk by irradiation forms a symplex, or a prosthetically-bound combination of enhanced antirachitic potency.

Compared to many other foods, milk, cream and butter are not, as has been charged (4), particularly potent sources of cholesterol. According to Bridges (9), the foods richest in this substance are egg yolk, beef and calf brains, kidney, and liver, which contain as much as 120 times the cholesterol found in whole milk. Butter, being a concentrate of milk fat, has about seven times as much cholesterol as milk, and cheese is also higher proportionately in this substance than is milk. At least 40 other foods, the cholesterol content of which is known, exceed milk in their proportions of cholesterol per 100 grams, and even such common foods as oranges, bread, lean beef, chicken, chocolate, ham, and lard equal or far exceed milk as a source of cholesterol, although the amount taken into the body would depend, of course, on the amount of

food ingested. The cholesterol content of a number of representative foods, as given by Bridges (9), is shown in the accompanying table. (Table I).

When foods containing cholesterol are eaten, all of this substance does not pass directly into the blood-

TABLE I

stream, but much of it is converted by the enzyme, cholesterase, into other substances, some of which are excreted, and some of which may go to the tissues in the form of esters. Most, if not all of the cholesterol in the body is, however, probably synthesized at an unknown site. "When all the facts are considered," says Bills (7) "it appears as likely as not that animal sterols, in so far as they are endogenous, originate in

the cells in which they occur." Vitamin D, on the other hand, is readily absorbed by the human body, and in the absence of the effects of sunlight, must be provided for infants and children in the form of appropriate food-stuffs or other materials, such as cod liver oil, other fish oils, vitamin D milk, and other substances containing one of the various forms of this vitamin.

A careful investigation of the effects of the "protective foods," defined as milk, eggs, fruit, vegetables and lettuce, on the incidence of degenerative disease was made several years ago by Langstroth (10) who reported that an analysis of the dietary histories of 501 patients revealed that the average diet contained only 12 per cent of these protective foods, and that the percentage incidence of degenerative disease increased as the percentage of protective food decreased. By means of a diet containing 70 per cent of protective food, improvement was brought about in 73 per cent of a group of 174 persons, usually by mitigation of distressing symptoms, and often by actual restoration of the integrity of the injured structure. Included among Langstroth's cases were arterio-sclerosis, as well as hypertension, myocardial degeneration, arthritis, chronic gastro-intestinal disease, diabetes, and migraine.

From the data presented, it would seem, therefore, that the small amount of cholesterol in milk is, if anything, a beneficial rather than a detrimental substance. In the light of modern knowledge, there seems to be no adequate reason for urging that normal persons attempt to curtail the amount of cholesterol in the diet (11). Certainly, there is no adequate evidence to incriminate milk as a factor in the development of any degenerative disease, including all forms of arterio-sclerosis (12).

Pure milk, whether certified or pasteurized, exhibits many dietary virtues, and so far as we know today, has no nutritional disadvantages but many advantages for the average, normal person, no matter of what age.

Studies in Gastric Motility

The Relation of the Size of the Meal to the Gastric Emptying Time in the Dog, Using a Meal Rich in Fat and Protein

By

EDWARD J. VAN LIERE, M.D., Ph.D.

and

CLARK K. SLEETH, B.S.

MORGANTOWN, WEST VIRGINIA

IN a recent paper (1) it was shown that in the case of man there was a definite relation between the size of the meal and the gastric emptying time. The standard meal used in man consisted of 15 Gm. of Quaker Farina. When the subject was given a meal twice the size of the standard meal, the average gastric emptying time was prolonged 16.83 per cent over the norm. And when a meal three times the size of the standard meal was given the subject, the average prolongation of the gastric emptying time was 23.33 per cent.

While these results were not unexpected, nevertheless, as far as we are aware, this was the first time that adequately controlled work had been done on the relation of the size of the meal to the emptying time of the stomach. In the study just quoted six subjects were used; five gave consistent results, that is, the larger the meal the longer was the gastric emptying time. One subject, however, was refractory; regardless of the size of the meal (within the limits of our investigation) the gastric emptying time was not prolonged.

It was thought worth while to perform some well

in five healthy vigorous dogs. These animals had previously been kept on a prescribed diet, were fed the same time each day and were trained for this type of work. The standard meal given these dogs was one which has been used in this laboratory for a number of years (2). It consisted of: 40 Gm. of hamburger steak, 10 Gm. of dried ground bread and 50 c.c. of milk. Fifteen Gm. of barium were added for fluoroscopic purposes. A number of determinations were made (only one, however, each day) and the average figure was used for the norm.

After the control gastric emptying time had been determined, the dogs were given a meal twice the size of the standard meal. From four to six determinations were made on each animal and the average figure was used.

They were then given a meal three times the size of the standard meal; from two to four determinations were made on this type of meal and the average figure was again used.

RESULTS

The accompanying table shows the results obtained.

TABLE I
The relation of the size of the meal to the emptying time of the stomach in the dog

No.	Standard Meal			Meal twice the size of normal			Meal three the size of normal		
	No. Tests	Emptying Time In Hrs.		No. Tests	Emptying Time In Hrs.	Increase %	No. Tests	Emptying Time In Hrs.	Increase %
1.	12	6.71		4	10.09	50.69	2	12.65	86.89
2.	12	5.62		4	9.17	62.50	2	12.12	107.65
3.	10	6.27		5	9.83	57.60	4	12.77	94.29
4.	9	6.58		1	9.17	50.69	3	12.16	81.79
5.	14	6.71		5	10.75	59.70	2	13.37	99.50
Avg.	12	6.38		5	10.07	58.14	3	12.40	93.88

controlled animal experiments so as to check the results obtained in man, especially since the gastric emptying time of one of the human subjects was not altered by increasing the size of the meal ingested. It was felt too that it would be of interest to ascertain whether a meal rich in fat and protein would give a comparable result to one relatively rich in carbohydrates.

METHODS

The normal gastric emptying time was ascertained

It will be seen that in case of the standard meal the average gastric emptying time for the five animals was 6.38 hours. When a meal, however, twice the size of the standard meal was used the average gastric emptying time was 10.07 hours—an increase of 58.14 per cent. And when a meal three times the size of the standard meal was used the average gastric emptying time was 12.40 hours or an increase of 93.88 per cent.

DISCUSSION

The results obtained with dogs were more striking than those obtained in man. It is realized that the re-

sults, however, are not strictly comparable since the composition of the meals, as previously mentioned, was quite different. The Quaker farina which was used in making the observations on man has the following composition: 77.7 per cent carbohydrate; 8.8 per cent protein; 0.8 per cent fat; the remainder consists of moisture, crude fiber and ash.* The meal used in studying the dogs, however, was relatively rich in fat and protein.

The dogs gave remarkably constant results; the larger meals in all of the animals in the series produced a prolongation of the gastric emptying time. The human case which showed no difference in gastric emptying time regardless of the size of the meal (at least within the limits of our investigation) was a distinct surprise to us. It would be of interest to know if there are many such individuals. The position, size and shape of the stomach when viewed fluoroscopically, of this subject, appeared normal in every respect. The subject, furthermore, did not complain of any subjective symptoms which are commonly associated with extreme hunger.

The unusual results obtained with this individual emphasize how hazardous it is to predict the outcome of investigative work even though the work appears quite predictable.

The physiological explanation which may be given of the fact that there is not a direct proportion between the gastric emptying time and the size of the meal is that the larger meal causes a greater distension of the stomach musculature which makes the contractions more effective. It has recently been shown that smooth muscle like striated muscle is capable of contracting more efficiently when it is under a certain amount of tension.

While it is possible that the pylorus at times may play an important role in gastric emptying time, its action must not be over emphasized. Recent work (3) has confirmed the earlier work that resection of the pyloric sphincter (Rangstedt's operation) in dogs or partial parasympathetic denervation of the pylorus had no effect on the gastric emptying time. The consensus of opinion seems to be that under normal conditions the pylorus does not greatly influence the gastric emptying time.

The results obtained with the dogs certainly corroborate those obtained on man. It may be said then that a large meal no matter whether it consists mostly of carbohydrates or is rich in fat and protein is capable of delaying the gastric emptying time longer than is a smaller meal. The data in this paper also point to the fact that a large meal rich in fat and protein is capable of delaying the gastric emptying time proportionally longer than would one consisting mostly of carbohydrates. The fact, however, that man was

used as a subject for one type of meal and the dog for another type of meal makes it necessary to accept this with a certain amount of reservation. Although the results are not strictly comparable the data are most suggestive.

SUMMARY AND CONCLUSIONS

Five healthy dogs were given a standard meal consisting of 40 Gm. hamburger steak; 10 Gm. of dried poulard bread and 50 c.c. of milk together with 15 Gm. of barium sulfate. The average gastric emptying time in the five animals for this meal was 6.38 hours. When a meal twice as large was given a prolongation of 58.14 per cent in the gastric emptying time was noted and when a meal three times the size of the standard meal was given a prolongation of 93.88 per cent was produced. All the animals reacted in the same way.

In the case of man (work previously reported) in which a meal was used consisting largely of carbohydrates, a meal twice the size of the standard meal produced a prolongation of the gastric emptying time of 16.83 per cent. A meal three times the size of the latter caused a prolongation of 38.33 per cent. One individual was refractory.

It is suggested that the reason the size of the meal was not directly proportional to the gastric emptying time was that the larger meal exerted increased tension on the gastric musculature and caused more effective gastric contractions.

The conclusions which may be drawn from this work are:

- (1). The results obtained in dogs confirm those obtained in man, namely that the larger the meal the longer the gastric emptying time (within the limits of our investigations).
- (2). The first named conclusion is true whether the meal consists largely of carbohydrates or is rich in fat and protein.
- (3). The data further suggest that a large meal rich in fat and protein is capable of delaying the gastric emptying time proportionally longer than one consisting chiefly of carbohydrates. (As different animals were used with the two different meals, the data must be considered merely as suggestive).
- (4). Finally these results give further experimental evidence to the well known fact that a large meal will delay the onset of hunger contractions.

How Does the Activity of the Cerebrum Affect the Work of the Internal Organs?

III. The Effect of Conditioned Reflexes on the Flow of Bile Through the Duodenal Ampulla

By

M. A. USSIEVICH

THAT the activity of the extra-hepatic biliary passages is influenced reflexly was established beyond doubt by the investigation of Bruno and Klodnitsky. Bruno showed in a very convincing manner how the emptying of the stomach influenced the output of bile; after extracting the stomach contents via a gastrotomy, the flow of bile decreased to zero, the flow being resumed on introducing the extracted contents into the stomach. This was confirmed later by Klodnitsky. In view of our results on the reflex connections between the cerebrum and the internal organs (Ussievich and Ussievich, Riss and Vvedensky), we have extended our investigations to determine the effect of cerebral activity on the outflow of bile, using the biliary fistula method improved by Pavlov and not removing the gall bladder.

Our observations have been made on a 25 kg. dog named "M. L." In making the biliary fistula a tongue-shaped piece of duodenum about the ampulla was excised and brought to the surface of the abdominal wall. With this modification the opening of the common duct was surrounded by muscle and mucosa, which became well insaculated in the abdominal wall.

feed the dog 600 c.c. of milk and then to subject the animal to different conditional studies. The conditioned stimuli were developed by the method of Pavlov, the salivary gland being used as an indicator and washing the mouth with 0.25 per cent HCl being used as the unconditioned stimulus.

The norms of bile output following milk were established beforehand. The curve of bile output was very uniform and the amounts excreted for a definite period (4 hrs.) was quite constant. As an example, data is presented in Table I for three different days. Data for dog "D" is also included. (Dog "D" was operated in Prof. I. P. Pavlov's laboratory and did not show scarring for ten months post-operatively). If one neglects the difference in the amounts of bile obtained in the two dogs, which difference may be due to differences in water balance, the "character" of the process of excretion is evident. The maximum rise in output occurs during the first hour, which is followed by a more or less abrupt decrease. As a rule, the maximum decrease occurs during the fourth hour after the meal. The latent period of the response varied from 5 to 7 minutes usually.

TABLE I
Bile obtained after 600 c.c. of milk

During many months of observation scarring about the fistula, as occurred in the dogs of Bruno and Klodnitsky, did not result. The scarring in the dogs of these observers caused them to report false evidence on the rate of bile output after the ingestion of meals, as will be observed on studying the data we give later.

We chose milk as the food stimulus because milk was shown by Bruno and Klodnitsky and later by Folbort to cause a large output of bile in the shortest possible time.

The method of experimentation in brief was to

In Chart 1 the difference between our results and those of Klodnitsky is shown. The difference depends probably on the scarring or the mechanical obstruction to outflow present in Klodnitsky's animals. This assumption appears to be supported by the observations of Folbort who reported an average latent period of response to milk of from 8 to 9 minutes.

After establishing the normal output of bile in response to milk in dog "M. L." the work with conditional stimuli was started. First, we observed the influence of the formation of a conditioned stimulus to the strokes of a metronome beating with a fre-

COMPARATIVE DATA ON BILE EXCRETION WHEN FEEDING MILK IN CASES DESCRIBED BY KLODNITSKY AND IN OUR CASES

Chart 1

quency of 160 per min., M. 160. Later, when the process of bile output to the conditioned stimulus took the trend "normal" for the dog, we applied a new stimulus, i.e. differentiation to the frequency of the metronome strokes, the new stimulus beating a frequency of 60 per minute, M. 60. Still later, we studied the effect of another conditioned stimulus, namely, a special device for the mechanical stimulation of the skin through touching it (the so-called "Kasalka"), which was attached to a well-shaven area of skin on the middle surface of the left thigh. As a rule, the number of touches amounted to 24 per minute (K. 24).

From January, 1935, to the middle of June, 1936, 175 tests were conducted, which were usually made every other day; in several instances tests were made daily or at 2 or 3 day intervals. During this period the animal was in good health and maintained its weight and appetite. The animal was fed bread and milk at about 4 p. m. and nearly all the bile excreted was fed, the dog taking its bile willingly.

The character of the curve of output obtained with the control or "normal" tests enabled us to draw the conclusion that the rapidity with which the bile

reached its maximum during the first hour depends on the effect of reflex influences arising in the duodenum on the biliary ducts, when milk unchanged by gastric juice passes into the duodenum during the first few moments after feeding (Bruno and Klodnitsky). This was of great interest to us because any changes in the latent period and the character of the curve of bile output could serve as indicators of the effects our experimentation (conditional stimuli) were producing. In fact, from the first experiment of applying conditioned reflexes the amount of bile obtained decreased from an average of 40 c.c. to 28 c.c. (25 per cent) during four hours of observation. Then, the character of the curve changed until after the fourteenth experiment. During this period of change, as a matter of fact, no two tests gave similar results, the latent period being at first from 4 to 6 min. and later as long as from 12 to 24 minutes, and the period of maximum output of bile occurred in the second and sometimes the third hour instead of the first (see tests 3, 5 and 11 and Chart 2). The third test in Chart 2 is of special interest because in control tests the maximum output of bile occurred during the first 15 minute period of

THE PROCESS OF BILE EXCRETION FROM THE MOMENT OF APPLYING THE FIRST CONDITIONED STIMULUS

Chart 2

THE PROCESS OF BILE EXCRETION SINCE THE MOMENT
THE FORMATION OF DIFFERENTIATION BEGAN

Chart 3

the first hour whereas in this test the output during the first 15 minute period was 0 c.c., the second was 5.5 c.c., the third 0 c.c. and the fourth 1.0 c.c. During the second hour the output for the first 15 minute period was 4.5 c.c., the second 5.0 c.c., the third and fourth periods together 10.0 c.c. In regard to the conditioned reflex activity during test 3, we observed considerable licking and a negative motor reaction to occur in response to the appliance of the conditioned stimulus. The *distortion of the normal curve* is also quite evident in tests 5 and 11. Thus, it is clear that the activity of the cerebral cortex initiated by the application of a conditioned stimulus reflexly influences the mechanisms concerned in the outflow of bile. The influence is not only manifest during the first few minutes of application of the conditioned stimulus, but is evident through the first and following hours.

In the fourteenth test it is to be noted that the process of bile outflow did not deviate from the normal in regard to latent period or the character of the curve. On applying in this test the conditioned stimulus M. 160 from 4 to 6 drops of parotid saliva was obtained during 20 seconds of isolated, conditioned reaction.

The effect of the application and the subsequent ap-

pearance of the "differentiated stimulus," M. 60, on outflow of bile was studied. On applying and then repeating the differentiated stimulus the normal process of bile outflow was again distorted for nine experiments. No two results were similar and the latent period was again increased. The data are shown in Chart 3 and Table II. In the first experiment (Chart 3), we observed a distorted curve. In the second experiment during the first hour, the following amounts of bile were obtained during each 15 minute period; first, 2 c.c.; second, 8 c.c.; third, 3.0 c.c.; fourth, 0 c.c. (In this experiment the value of the salivary response to the differentiated stimulus, M. 60, was greater than to the conditioned stimulus M. 160). The distortion was again repeated in the 3rd, 5th, 7th and 8th experiments, but in the 9th the normal curve of output for each 15 minute period during the first hour was restored, as well as the normal curve of hourly outflow for the four hour period (see Chart 3 and Table II). Further, the maximum outflow of bile frequently occurred in the 4th hour rather than the first, which occurred in the 1st and 3rd experiments; in the 2nd and 8th the maximum occurred in the 3rd hour and in the 4th in the 2nd hour. Thus, it is evident that when

Chart 4

differentiation between the two stimuli was being formed, which required cerebral activity, the normal outflow of bile was disturbed.

As usually occurs when a differentiation between two stimuli (M. 160 and M. 60) is being formed an undulating course is observed. In regard to this, at-

having been fed to cause a flow of bile. It was found that the application of the conditioned stimulus, M. 160, definitely altered the latent period and the characteristics of the curve of response of bile outflow after milk for a period of fourteen tests, after which a normal response occurred. The introduction of a

TABLE II

The bile output for each 15 minute period during the first hour when the "differentiated" stimulus M.60 was applied

No. of Experiments	1st 15 Min. Period c.c.	2nd 15 Min. Period c.c.	3rd 15 Min. Period c.c.	4th 15 Min. Period c.c.	Remarks
3rd	4	3	0	0.5	Salivary response was much higher than to conditioned stim. M.160.
5th	0	7	5	2	Incomplete discrimination between conditioned and "diff." stimuli.
7th	5	9	8	1	Practically no discrimination.
8th	0	4	2	4	Complete discrimination between the two types of stimuli.
9th	7	8	3	2	Weak disinhibition.
10th	5	5	4	3	Complete and steady discrimination.

tention should be directed to Chart 4, which shows the salivary response. In the first experiment a lower secretory effect is obtained to the "differentiated" than to the conditioned stimulus. During the two following experiments an increase was obtained. In the 4th experiment when applying the "differentiated" stimulus for the 7th time, we observed no secretion; but we observed a residue of the motor reaction characteristic of the conditioned stimulus (dog licks its lips, gnaws the device for applying the acid, and turns its head aside as though acid had actually been applied) followed by pronounced reactions of an inhibitory character. The 5th and 6th experiments yielded somewhat similar results. Disinhibition (inhibition of inhibition) was observed in the 7th experiment. The first clear evidence of discrimination between the two stimuli was observed in the 8th experiment. A slight disinhibition occurred during the 9th and a complete and steady discrimination began with the 10th experiment.

When the conditioned reflex activity shows the greatest range, the deviations from the normal output of bile are greatest. For example, in experiment 1, Chart 3, when the stimulus M. 60 gives a lowered conditioned reflex (Chart 4), the bile output is at a high level for four hours and the maximum is during the fourth hour. In experiments 2 and 5, the output to M. 60 is excessively high and of a character never observed in the dog before or after. The results of experiment 3 are of special interest because of the marked irregularity in bile output.

DISCUSSION

The effect of cerebral activity on the outflow of bile has been studied by the application of the method of conditioned reflexes on a dog with a permanent biliary fistula so prepared as to avoid artifacts due to scarring or mechanical obstruction of the ampulla of the common duct. The normal outflow of bile from the fistula on the ingestion of 600 c.c. of milk was determined. Then, the salivary gland was conditioned to a stimulus, the stimulus being a metronome beating at a frequency of 160 per minute, the milk, of course,

stimulus (M. 60) that had to be differentiated from the conditioned stimulus (M. 160) caused a marked distortion of the curve of the outflow of bile from the fistula for a preliminary period of nine experiments.

These results show that the state of cortical activity, the process of "learning," has a definite effect on the outflow of bile from the biliary passages, which must be due to a true "dyskinesia" (Bergmann, Westphal, Ivy and others). This may be considered, as others have previously done as evidence, of the importance of dyskinesia in the etiology of diseases of and symptoms from the gall bladder and biliary ducts.

The changes in the outflow of bile, or the dyskinesia may be related to changes in gastric secretion or motility, since we found in our previous experiments on a Pavlov pouch that gastric secretion was decreased during the development of a conditioned reflex, and it is known that biliary outflow is related to gastric secretion and motility. Either this explanation holds or the musculature of the extra-hepatic biliary passages is directly affected through its extrinsic nerves. It is suspected that both influences operate to effect the changes observed.

CONCLUSIONS

1. During the formation of a conditioned reflex the volume outflow of bile from the biliary passages in response to the ingestion of milk is reduced, the latent period of outflow of bile in response to milk is lengthened, and the characteristics of the curve during the first and succeeding three hours is distorted from the normal.

2. The application of a stimulus that must be differentiated from the conditioned stimulus markedly distorted the normal response to milk. This is best explained by assuming that a true biliary tract dyskinesia occurred.

The Prevention or Healing of Experimental Peptic Ulcer in Mann-Williamson Dogs with the Anterior Pituitary-Like Hormone (Antuitrin-S)

A Preliminary Report

By

DAVID J. SANDWEISS, M.D., HARRY C. SALTZSTEIN, M.D.

and

AARON FARBMAN, M.D.
DETROIT, MICHIGAN

ONE of us (D. J. S.) has made the clinical observation that pregnancy has a beneficial effect upon peptic ulcer. Women who have active peptic ulcers, both clinically and roentgenologically become symptom-free with the onset of pregnancy. Activation of a pre-existing ulcer during pregnancy is rare. Discussion with several experienced obstetricians confirmed this; they uniformly did not remember any patient with ulcer or its complications during pregnancy. The records at Harper Hospital for ten years did not show any case of admission of a pregnant woman with active ulcer symptoms or complications.

A review of the literature confirmed this impression.

Hurst and Stewart (1) state: "There is no doubt that pregnancy exerts a favorable influence on the symptoms of ulcer, especially of the stomach, and in some cases it appears to lead to actual healing apart from any specific treatment."

Crohn (2) says in a foot note: "Ulcer cases in women usually do very well during pregnancy. The

ulcer usually goes into intermission and gives few, if any, symptoms of activity."

Other similar reported observations are:

Adair and Stieglitz (3): "Fortunately, patients who have had symptoms of peptic ulcer before pregnancy are usually comfortable during pregnancy, and the ulcer becomes inactive."

"Patients with visceroptosis commonly complain of symptoms referable to the duodenum. Pregnancy usually causes an improvement or disappearance of these obstructive like signs. Duodenal ulcer is very uncommon during pregnancy."

Anderodias (4): "Pregnancy does not aggravate gastric ulcer and delivery has little effect upon its course."

Balint (5): "It is a clinical experience not at all rare that ulcer improves during pregnancy. The symptoms cease and very frequently the ulcer also heals."

Westphal (6): "There is distinct recession of ulcer symptoms in pregnancy."

Blakeley (7): "Some painful intra-abdominal conditions may be improved by or during pregnancy—abdominal hernia, visceroptosis, gastric ulcer."

Dog No. 110 (c); high power showing beginning of epithelial covering of the ulcer at its edge; fibroblastic proliferation at base, and newly formed blood vessels.

Dog No. 120 (b); Proliferative changes at edge of ulcer; fibroblastic proliferation at base with newly formed blood vessels.

*From the Surgical Laboratory, Harper Hospital. Aided by a grant from the Mendelson Fund. Theelin and Antuitrin-S were furnished through the courtesy of Parke-Davis & Company.

Dog No. 120 (a) died 44 days post-operatively. One c.c. of Antuitrin-S (anterior pituitary-like hormone) was given from the day of operation to the day of death. Photomicrograph showing epithelial covering at edge of ulcer. Attempt at healing.

Mulsoy and Brown (8): Refer to the "rare complication of peptic ulcer in pregnancy."

Adair and Stieglitz (3): "In twenty years at the Minnesota General Hospital no case of peptic ulcer in pregnancy had to be treated."

Szenes (9) was impressed with the rarity of operations for peptic ulcer during pregnancy while serving as assistant in the large gastric clinics of von Eiselsberg and Finsterer.

Mussey (10) of the Mayo Clinic reported 370 opera-

tions of necessity during pregnancy over a period of ten years: Two were for peptic ulcer.

The reasons given are various:

(1). The support offered to the stomach by the rising uterus. (Hurst and Stewart; Adair and Stieglitz; Blakeley; Szenes). The strain on the lesser curvature should thereby be relieved, thus improving local circulation. (Hurst and Stewart).

(2). The blood and tissues tend to become more alkaline. (Balint).

(3). Increased fat padding in pregnant women. (Szenes).

(4). A patient anemic and in poor health from ulcer is unlikely to become pregnant.

This rarity of ulcer symptoms in pregnancy is all the more striking, since "in general, the pregnant abdomen seems to be more prone to painful sensations than the non-pregnant." (Blakeley).

It is common clinical knowledge that disease of the liver and bile passages, ptosis or obstruction of the intestinal and urinary tracts and inflammatory processes are all made worse by pregnancy. The rise and pressure of the gravid uterus has been held responsible for many and varied symptoms.

Dog No. 126 died 60 days post-operatively. One c.c. of Antuitrin-S (anterior pituitary-like hormone) was injected daily beginning with the day of operation to the day of death. No ulcer. The gastrojejunal stoma is shown in the photograph.

Dog No. 43; untreated (*control*); died 51 days post-operatively. Perforated ulcer.

ENDOCRINOLOGICAL RELATIONSHIP

Szenes (9) having found twelve gastric and seven duodenal ulcers in pregnant women, and having carefully reviewed the literature up to 1924 made these observations:

(a). Women who have never become pregnant come to operation for ulcer at an earlier average age than those who have had one or more pregnancies.

(b). Ulcer patients who get better during pregnancy are those who have little or no vomiting, while those who do not improve or get worse have frequent vomiting.

(c). In only 10% of cases was the onset of ulcer symptoms at the time of the menopause. "This small percentage speaks for the fact that the ovarian function plays a role in the genesis of ulcer."

Winkelstein (11) in 1935 observed that ulceration of abdominal wall occurred about the opening of Pavlov pouches in two of his experimental dogs. These healed during oestrus. Another ulceration which started during pregnancy was healed after ten daily injections of theelin (present actively during oes-

trus). Lactation again broke open the ulceration, and it was again healed with Theelin. Then using antuitrin-S injections, it promptly broke open again. There seemed to be no relation between the secretory activity of the pouch and the amount of ulceration.

He thought these results significant, and that they might have a possible relationship to peptic ulcer in man, and perhaps to the overwhelming preponderance of human ulcer in the male.

Thus, there are several brief reports of pregnancy having a beneficial influence upon peptic ulcer. Various explanations have been offered. Szenes (9) in 1924 and Winkelstein (11) in 1935 suggested that there may be an association between the ovarian function and peptic ulcer.

METHOD OF STUDY

On the basis of the above impressions we decided to test the effect of the hormones which are found abundantly during pregnancy, on experimental jejunal ulcers in dogs.

The standard Mann-Williamson operation (12) was performed. The pylorus was sectioned and the distal end was inverted. The open end of the stomach was anastomosed to the jejunum 10 cm. beyond Treitz ligament (after dividing the jejunum at this point). The end of the jejunum draining the duodenal juices was then anastomosed to the terminal ileum about 20 to 30 cm. above the ileo-cecal valve. Fine silk was used throughout, with no clamps. The dogs were starved 24-28 hours before operation. Ether anaesthesia was used. They were given water as tolerated

Dog No. 78 died 42 days post-operatively. One thousand international units of theelin in oil were injected daily beginning with the day of operation to the day of death. Perforated ulcer.

Dog No. 119 died 57 days post-operatively. One c.c. of *antuitrin-S* (anterior pituitary-like hormone) was injected daily beginning with the day of operation to the day of death. No ulcer.

for four days post-operatively (plus saline subcutaneously as needed, 3-4 days) and then placed on a diet consisting of finely chopped hamburger, bread and milk. The reason for this was to allow no roughage.

The Mann-Williamson operation of surgical duodenal drainage produces ulcer in 95-100% of animals. Although many investigators have worked with these ulcers, no method or procedure has so far been done which completely heals or prevents the development of these ulcers (except fundusectomy with high-purine, high-carbohydrate, and high-vitamine diet reported by Fauley and Ivy (13)). With the latter exception the dogs invariably die, usually within two or three months after the operation. Post mortem examination shows a chronic ulcer in the jejunum, always opposite the stoma, $\frac{3}{4}$ -1 cm beyond the suture line where the unprotected jejunal mucosa first comes in contact with the acid gastric stream. There is no evidence of healing.* There is marked bleeding and frequently perforation of all the coats of the jejunum.

Previously we (14) reported that 12 control dogs who had had the Mann-Williamson operation developed typical jejunal ulcer, and 13 dogs treated with histidine also developed jejunal ulcers.

To determine the effect of sex hormones found abundantly during pregnancy upon Mann-Williamson ulcers we selected theelin (estrin) and antuitrin-S for two series of dogs.

Theelin, as is well known, is a hormone produced

by the Graafian follicle and acts upon the endometrium stimulating its development up to the interval state (i.e. the progesterin or degenerative phase) of the menstrual cycle. Normally, according to Gustavson, Hays and Wood (15), a woman excretes 13,000 international units of theelin during a month. This excretion varies and they found a peak of 900 international units occurring in a single day during the cycle. During pregnancy the excretion of estrogenic substances in the urine increases as gestation progresses and most investigators at the present time consider that the peak excretion in the latter part of the third trimester will range from 150,000 to 200,000 international units per liter of urine.

Antuitrin-S is an anterior pituitary-like hormone believed to be produced in large amounts by the chorion of the developing embryo. It is the presence of large amounts of the pituitary-like substance in the urine which is the basis of the pregnancy tests. Normally, according to Wolf (16), the urine of non-pregnant women (except at the inter-menstrual period) and of men contains very little pituitary-like hormone; but after the second day of the first missed period in a pregnant woman it is already present in sufficient quantities to get a positive Asheim-Zondek test. The amount generally increases until the 30th to 36th day when, as shown by Evans, Kohls and Wonder (17), as much as 130,000 to 150,000 rat units (or even a million rat units) may be excreted in urine within 24 hours. There is a precipitate decrease immediately after the peak excretion but a level of 5-10

Dog No 110 died 106 days post-operatively. One c.c. of *antuitrin-S* (anterior pituitary-like hormone) was injected daily beginning with the day of operation to the day of death. Superficial ulcer.

*"I should say that there is no evidence of healing in dogs dying within 12 weeks postoperatively. In dogs surviving longer, evidence of healing may be observed at some point about the edge of the ulcer." Ivy, A. C. Personal Communication.

Section of ulcer found in Dog No. 110; (b) base of ulcer rests on outer layer of muscle and is composed of fibroblasts and newly formed blood vessels with a thin pyogenic membrane over surface. The epithelial cells at periphery of the ulcer are in good condition, showing beginning covering of the ulcer just at its edges.

thousand rat units daily is maintained until the termination of pregnancy.

Fifteen Mann-Williamson dogs were injected subcutaneously daily with 1,000 international units of theelin in oil from the date of operation to the date of death. Fifteen Mann-Williamson dogs were injected daily with 1 c.c. of antuitrin-S (100 rat units) from the date of operation to the date of death. The

diet used was the same for both of these series as well as for the control series. The dogs were not sacrificed except occasionally when found in extreme moribund condition and death was expected during the night. All dogs died either of peritonitis following perforation of the ulcer or of a disturbance in nutrition as a result of the duodenal contents being diverted into the terminal ulcer.

RESULTS

(1). Of the twelve Mann-Williamson control dogs all died with typical jejunal ulcers within 16.1 weeks. Nine (75%) died of peritonitis (following perforation) or hemorrhage. None of the ulcers showed evidence of healing. (Table I).

(2). Of the fifteen dogs injected with theelin all developed the typical jejunal ulcers. All died within 10.6 weeks from the date of operation. Eleven (73%) died of peritonitis (following perforation) or hemorrhage. None of the ulcers showed evidence of healing. (Table II).

(3). Of the fifteen Mann-Williamson dogs treated with antuitrin-S seven (47%) died with jejunal ulcers. Four of these (27% of the total) showed definite evidence of healing microscopically, i.e. fibroblastic proliferation, newly formed blood vessels, a very thin pyogenic membrane, and early covering of the ulcer surface at the margin. Only one of the seven (7%) died of a perforated ulcer. The remaining eight (53%) showed no gross or microscopic evidence of jejunal ulcers (Tables III and IV). The dogs died of inanition as a result of the duodenal contents being diverted into the terminal ileum.

Antuitrin-S, therefore, had either prevented ulcer formation, completely healed the ulcer, or caused healing to take place in (80% of the Mann-Williamson dogs. Five more Mann-Williamson dogs are still alive and are being treated with antuitrin-S. One is still

ing macroscopically. In only one instance did the ulcer perforate through all the coats. The jejunum had the appearance of being healthier than in the previous controls.

Fig. 1 shows three curves representing the percentage survival-time of the untreated (controls), theelin treated and antuitrin-S treated Mann-Williamson dogs. These were constructed similar to those of Ivy's (18) in interpreting the prophylactic effectiveness of various therapeutic measures in experimental peptic ulcer. It shows that 100% of the untreated (control) and theelin treated dogs died with ulcers within 16.1 and 10.6 weeks respectively. Of those treated with antuitrin-S only 47% of the dogs died with ulcer.*

DISCUSSION

DeBaakey (19), reporting his results on the relative protective value of alkaline duodenal juices in experimental ulcers in dogs concludes that "of all the constituents of the alkaline duodenal juices, bile has the most significant and effective influence in preventing the formation of jejunal ulcer; the duodenal secretion, the succus entericus, is the least important, and the pancreatic juice is midway between the two in this respect."

In the Mann-Williamson dogs the duodenum and its alkaline contents is diverted into the terminal ileum, thus

depriving the stomach and jejunum of all the alkaline duodenal fluids (including the bile and pancreatic juice). Of our untreated (control), theelin treated, and histidine treated Mann-Williamson dogs all developed ulcers. In our antuitrin-S-treated-Mann-Williamson dogs 53% did not develop ulcers and an additional 27% though having ulcers showed definite evidence of healing—this, in spite of the absence of the alkaline duodenal fluids, bile and pancreatic juice. Further work is to be done to determine the effect of antuitrin-S on gastric acidity, gastro-intestinal motility and tissue healing. It is also important to determine the effect of the peptone fraction (to which the anterior pituitary-like hormone is attached) on Mann-Williamson ulcers.

On the basis of the clinical observation (that pregnancy has a beneficial effect on peptic ulcer) and on the above experimental results (that antuitrin-S has apparently a preventive or inhibitive effect on Mann-Williamson ulcers) the improvement in ulcer noted during pregnancy may have a relationship to the large amounts of antuitrin-S present in the body at this time.

A lack or deficiency of anterior pituitary-like hormone or decreased production of the gonadotropic hormone of the anterior pituitary gland in the non-pregnant subject may be a factor in the genesis of peptic ulcer in man. The anterior hypophysis is normally active until the stage of post-adolescence is reached, prior to which peptic ulcer is rare. Furthermore, the lower incidence of peptic ulcer in the female, contrasted with a very high incidence in the male during maturity, might be explained by a greater glandular activity in the female reproductive zone, due to her cyclic physiologic phenomena. In the female, the reproductive cycle may serve in some measure as a preventive of peptic ulcer.

SUMMARY

(1). There is clinical evidence that ulcer and its complications are infrequent during pregnancy.

(2). The attempt was made to prevent or heal experimental ulcers (Mann-Williamson dogs) by daily injections of estrogenic and gonadotropic hormones which are known to be excreted in greatly increased amounts during pregnancy.

(3). Twelve untreated (control) Mann-Williamson dogs all died with typical jejunal ulcers. 75% died of peritonitis following perforation. There was no evidence of healing.

(4). Fifteen Mann-Williamson dogs treated with theelin all died with typical jejunal ulcers. 73% died of peritonitis following perforation. There was no evidence of healing. These dogs died sooner than the control dogs which appears to indicate that theelin accelerates perforation as compared with the control series.

(5). Fifteen Mann-Williamson dogs were treated with antuitrin-S. 53% of the dogs failed to show ulcer at post-

TABLE IV
The prevention or healing of Mann-Williamson ulcers with Theelin and Antuitrin-S

	No. of Dogs	Died with Jejunal ulcer	Death due to Perforation or Hemorrhage	Prevention of Ulcer	Definite Healing of Ulcer
Control	12	12 (100%)	9 (75%)	0	0
Theelin	15	15 (100%)	11 (73%)	0	0
Antuitrin-S	15*	7 (47%)	1 (7%)	8 (53%)	4 (27%)
80%					

*Five more Mann-Williamson dogs treated with Antuitrin-S are still living. See Table III.

*The horizontal line in Fig. 1 indicates the survival time in weeks. The vertical line represents the percentage of the total animals, which died and post mortem showed ulcer.

mortem examination (death due to inanition). Of the seven dogs that died with ulcer, four (27% of the total) showed definite evidence of healing microscopically, as fibroblasts proliferation, newly formed blood vessels, a thin pyrogenic membrane, and early covering of the ulcer surface at the margins. A total of 80% of the Mann-Williamson dogs either had their ulcers prevented, healed, or healing during antuitrin-S treatment. Only one died of a perforated ulcer. (See Table IV).

(6). The improvement in peptic ulcer noted during

pregnancy may have a relationship to the large amounts of antuitrin-S present in the body at this time.

NOTE: The authors are indebted to Dr. Plinn F. Morse, pathologist, Harper Hospital, and Dr. Donald Beaver, pathologist, Woman's Hospital, Detroit, Michigan, for the gross and microscopic examinations of the specimens obtained at autopsy; also to Dr. E. A. Sharp of Parke Davis & Co. and Dr. A. C. Ivy for their many courtesies and valuable advice in the course of this work.

Mr. Lee Carrick assisted in this work.

Further Attempts to Produce Achlorhydria

By

A. J. ATKINSON, M.S., M.D.

and

A. C. IVY, Ph.D., M.D.*

CHICAGO, ILLINOIS

IN a previous report we have indicated the desirability of producing achlorhydria experimentally (1). We have continued the investigation with the study of various other substances including:

- I. Organo-therapeutic products
 - A. Theelin
 - B. Emmenin
 - C. Pitressin and Pituitrin
 - D. Pepsin
 - E. Larostidin
- II. Drugs acting by remote effect on body chemistry
 - A. Potassium citrate
 - B. Monobasic sodium phosphate
 - C. Sodium thiosulphate
- III. Dyes
 - A. Indigo Carmine
 - B. Toluidine Blue
 - C. Methylene Blue
 - D. Congo Red
 - E. Eosin

IV. Local irritants

- A. Silver nitrate
- B. Sodium selenite
- C. Cobalt acetate

METHOD OF EXPERIMENTATION

Experiments were performed on dogs with Pavlov pouches and with patients with chronic duodenal ulcer. Two types of gastric stimulants were used—food and histamine. Fractional test meals of crackers and water, and subcutaneous injections of 0.5 mgm. of histamine (ergamine acid phosphate, "Imido-Roche") were employed as the gastric secretory stimuli in fasting patients. The dogs were fed 200 grams of meat, 200 c.c. of milk, and 200 c.c. of water, or given 1 mgm. of histamine subcutaneously. Samples were withdrawn from the stomach of the patients every ten minutes for two hours after the test meal or histamine injection, and for seven hours from the pouches of the dogs after a meal, and for two hours after histamine. Control samples were taken before any procedure was instituted. The acidity of the stomach contents was determined by titration with

0.1% Normal NaOH, Topfer's reagent and phenolphthalein being used as indicators.

ORGANOTHERAPY PRODUCTS

Certain endocrine products have been suggested for use in the treatment of peptic ulcer on the basis of theoretical deductions. Strauss and Castle (2) reported a decline in gastric acidity in women during the second trimester of pregnancy. During the last month of pregnancy the acidity levels rose to those observed in the third month. Van Zant and Alvarez (3) reported tendency for gastric acidity to be low during menstruation. Hellebrandt and Brogdon (4) using daily alcohol test meals observed a marked decrease of free hydrochloric acid, but relatively little change in total acidity, during a normal menstrual period. The corpus luteum involutes about the eighth month of pregnancy. The luteal hormone is secreted in substantial amounts during the early months of pregnancy, and in the last half of the menstrual cycle. Theoretically the corpus luteum might be responsible for the diminution in acidity observed during pregnancy and menstruation. Manville and Monroe (5)

noticed that pregnant dogs did not give the normal gastric secretory response to histamine. They gave dogs corpus luteum without observing an inhibition of the gastric secretory response to pilocarpine.

THEELIN

Winkelstein (6) reported that injections of theelin hastened the healing of abdominal wall ulcers occurring about the opening of Pavlov pouches in dogs. He suggested that theelin might also be of value in the treatment of peptic ulcer. We were interested in knowing whether theelin might influence the gastric secretory response to histamine or to a meal in dogs and in patients with duodenal ulcer.

Two thousand units of theelin were given daily for one month intramuscularly to two dogs (10-12 kilos in bd. wt.) with Pavlov pouches. The secretory response to a meal and to histamine was unchanged by the administration of theelin (Table I). The benefit in the healing of abdominal wall ulcers in the dogs with Pavlov pouches (observed by Winkelstein) apparently was not due to a diminution of acid secretion.

TABLE II

The effect of emmenin on the gastric secretory response to histamine and a fractional test meal. (Average results to two patients)

	Total Volume Output c.c.	Maximum Free Acid Clinical Units	Maximum Total Acid Clinical Units	Total Acid Output mgms.
Meal				
Before emmenin		60	102	
After 12 c.c. emmenin daily for 14 days		56	72	
Histamine				
Controls	215	95	119	339
Response to histamine after 12 c.c. emmenin daily for 14 days	90	102	122	168

TABLE III

The effect of daily injection of 5 c.c. of larostidin on the secretory response of the Pavlov pouch to a meal

	Total Volume Output c.c.	Maximum Free Acid Clinical Units	Maximum Total Acid Clinical Units	Total Acid Output mgms.
Average of 10 control experiments on dog No. 1	130	145	168	661
Average of 10 experiments on dog No. 1 during and after daily larostidin injections for 1 month	128	144	164	662
Average of 10 control experiments on dog No. 2	117	136	155	648
Average of 10 experiments on dog No. 2 during and after daily larostidin injections for 1 month	116	134	151	644

The effect of theelin also was studied on a patient with duodenal ulcer who was having menopausal symptoms. Ten thousand units of theelin were given intramuscularly every day for twenty days. The gastric secretory response to a fractional test meal and to histamine was not modified by the theelin treatment.

EMMENIN

Collip (7) discovered emmenin, another substance having a powerful estrogenic potency. Our experience on the comparative effects of emmenin and theelin on menstrual edema (8) led us to believe that there also might be further physiologic differentiation of these substances in their effects on the gastric secretion. We compared the results of fractional test meals and histamine before and after giving 12 c.c. of emmenin daily for two weeks to two patients with duodenal ulcer. The maximum free and total acidity values of repeated tests were essentially unchanged but the volume and milligrams of acid secreted during the test period were somewhat diminished (Table II).

PITUITRIN AND PITRESSIN

Pituitary extract (posterior lobe) was reported to have brilliant effects in gastric hyperacidity and peptic ulcer by Drouet and Simonin (9). They claim to have demonstrated that pituitary extract has the definite effect of diminishing gastric acidity. On the other hand Dodds, Noble and Smith (10) reported that the posterior lobe of the pituitary contains a substance which, when injected, induces a severe lesion of the acid-bearing area of the stomach in rats. They suggested that either there was a direct toxic action on the cells or that the secretion of hydrochloric acid was stimulated to a damaging extent.

Because of these interesting and diametrically opposite findings of the action of the posterior lobe, pituitary extract, we were interested in studying the effect of subcutaneous injections of pituitrin and

pitressin on the gastric secretory response of the Pavlov pouch to a meal.

Pituitrin and pitressin in 1 c.c. doses (Parke Davis) were given by subcutaneous injections to two dogs with Pavlov pouches for two weeks. There was no essential change in the gastric secretory response to a meal.

PEPSIN

Glaessner (11) and others (12) have reported benefit to accrue in the treatment of gastric and duodenal ulcers, and a diminution in gastric acidity from the subcutaneous injection of pepsin. We obtained ampules of this substance, supposedly identical with that used by Glaessner. The pepsin was given to two dogs with Pavlov pouches in increasing amounts up to 3 c.c. daily for three and one-half months. We observed no change in the secretory response of the Pavlov pouches to a meal. We also observed no change in the peptic activity of the gastric juice as measured by the Metz test. We realize that negative results in dogs necessarily do not negate positive findings in patients with peptic ulcer.

HISTIDINE MONOHYDROCHLORIDE

Weiss and Aron (13) in 1933 introduced the parenteral injections of histidine hydrochloride in the treatment of peptic ulcer. A number of reports concerning the efficacy of this treatment have since appeared. We considered it pertinent to investigate the effect of histidine on the gastric secretory response of dogs and patients with duodenal ulcer to histamine and to a meal.

Five c.c. of larostidin (4% solution of laevo-histidine monohydrochloride) were injected daily intramuscularly into two dogs for one month. There was essentially no change in the gastric secretory response to a meal or to histamine after larostidin injections (Tables III and IV).

To study the effects of histidine on the acid secre-

TABLE IV

The effect of histidine (larostidin) on gastric secretory response to histamine in three patients with duodenal ulcer

	Total Volume Output c.c. 2 hrs.	Maximum Free Acid Clinical Units	Maximum Total Acid Clinical Units	Total Acid Output mgms.
Average of controls	433	78	90	608
After 30 injections of histidine	625	62	78	812

tion of man, tests were made on three patients with duodenal ulcer by giving injections of 5 c.c. larostidin daily by intramuscular injection for one month, and comparing the gastric secretory response to histamine in three experiments before beginning larostidin and three experiments at the completion of the course of treatment. There was a slight decrease in the maximum free and total acidity titres, but an increase in the volume and total milligrams of acid output in response to histamine stimulation. These changes are without significance (Table V).

A patient with duodenal ulcer with "continuous hypersecretion" (an active secretion while fasting) was studied before and after thirty injections of histidine without any gastric secretory stimulus. The fasting stomach contents were somewhat decreased in acidity, but the volume or rate of secretion was greater (Table VI).

If histidine is of value in the treatment of peptic ulcer, its value apparently is not due to a diminution of acid secretion.

DRUGS ACTING BY REMOTE EFFECT ON BODY CHEMISTRY

Most studies of the effect of alkalis on gastric secretion have been concerned with sodium bicarbonate. Some investigators have thought that sodium bicarbonate not only neutralizes the hydrochloric acid in the stomach, but also reduces the amount of acid secreted in the stomach. Boyd (14) demonstrated that massive doses of sodium bicarbonate depressed gastric secretion in dogs. With doses within the limits of ordinary antacid medication the secretory response to a meal was slightly greater than without the alkali. He also stated that massive doses depressed the gastric secretory response to histamine, whereas doses up to one gram per kilogram of body weight did not affect the secretory response unless given in five per cent concentration.

We thought that since sodium bicarbonate had a local neutralizing effect in the stomach, we would study the effects of potassium citrate, in which the local action is absent, but the systemic action is that

of an alkali. Potassium citrate is converted to potassium bicarbonate chiefly after absorption and combustion. Certain side actions might be expected such as the inactivation of calcium in the diet by the citrate forming a double salt with calcium, which does not liberate calcium ions. The administration of the potassium ions might also cause a change in the sodium potassium ratio. There also might be some diuretic and a slight cathartic action.

To determine whether potassium citrate might influence the gastric secretion, 20 gms. of potassium citrate were given daily with a meal to two dogs for one month. Twenty-four eight-hour experiments on the gastric secretory response to the meal were studied during this time to determine whether an acute or cumulative effect accrued. The 20 gms. of potassium citrate given daily for one month did not depress appreciably the gastric secretion except when nausea and vomiting occurred. The carbon dioxide combining power of the blood at the end of the month was 45.7 c.c. per 100 c.c. of blood.

MONOBASIC SODIUM PHOSPHATE

MacLean and Griffiths (15) showed that the introduction of sodium acid sulphate into the stomach prevents the secretion of hydrochloric acid until sufficient neutral chloride is secreted to dilute the gastric contents to 0.2% HCl or lower. Hydrochloric acid is then secreted.

We were interested in studying the effect of monobasic sodium phosphate on gastric secretion. Twenty grams were mixed with the food and given daily over a period of six weeks to one dog. Another dog was given only 15 gms. because 20 gms. caused vomiting in this dog.

The gastric secretion of the Pavlov pouch following the meals containing monobasic sodium phosphate was depressed. The monobasic sodium phosphate decreased the appetite of the dogs and interfered with the eating of meals (Table VII). No cumulative effects on the gastric secretion were observed.

SODIUM THIOSULPHATE

Intravenous injections of one gram of sodium

TABLE VI

The effect of histidine on the basal gastric secretion in a patient with duodenal ulcer and "continuous hypersecretion." (Fasting stomach contents were removed every ten minutes for two hours)

	Total Volume Output c.c. Per Hr.	Maximum Free Acid Clinical Units	Maximum Total Acid Clinical Units	Total Acid Output mgms. Per Hr.
Average of 3 experiments on 3 successive days before histidine	224	52	64	48
Average of experiments on 3 successive days after 30 injections of histidine	464	32	52	66

TABLE VII

The effect of administration of monobasic sodium phosphate on gastric secretion in the Pavlov pouch dog

	Total Volume Output c.c.	Maximum Free Acid Clinical Units	Maximum Total Acidity Clinical Units	Total Acid Output mgms.
Administration of 15 gm. to dog No. 1				
Average of 13 control experiments	34	94	122	131
After administration of 15 gm. monobasic sodium phosphate daily for six weeks	31	65	106	104
Administration of 20 gm. to dog No. 2				
Average of 7 control experiments	74	123	142	313
After 20 gm. monobasic sodium phosphate	44	108	125	175

thiosulphate in 15 c.c. solution ten minutes after a meal produced no effect on the gastric secretion of Pavlov pouches.

DYES

The excretion of parenterally administered dyes into the stomach has been considered to be closely associated with the secretion of hydrochloric acid (16). We attempted to find a dosage of various dyes that might on intravenous administration stop the secretion of hydrochloric acid by the stomach. The dyes used were Toluidin Blue (25 c.c. of a 1% solution), Methylene Blue (25 c.c. of a 1% solution), Congo Red (50 c.c. of a 1% solution), Eosin (50 c.c. of a 1% solution), and Indigo Carmine in saturated solution. All but the last named dye are excreted into the Pavlov pouch after intravenous injection. No dosage could be found to stop the secretion of hydrochloric acid by the stomach unless a toxic dose were given. Intravenous injection of 10 c.c. saturated solution of Toluidine Blue produced no change in the secretory response of the Pavlov pouch of dogs but 15 c.c. caused death of one dog.

LOCAL IRRITANTS

Silver nitrate because of its astringent, caustic and antiseptic effect has long been used in lavaging the stomachs of patients with gastritis or peptic ulcer. Kaufmann (17) used silver nitrate for lavaging the stomach in patients with the so-called hyperacidity syndrome. He and Baibakoff (18) both stated that although the symptoms were relieved, the application of silver nitrate did not necessarily reduce the secretion of gastric juice. Although a lowering of the acidity occasionally was observed, such lowering was not the rule, and in some there was a higher degree of acidity after treatment even though the symptoms had been removed. He explained the beneficial results on the basis of finding an insufficiency of mucus before

treatment and an increase afterwards. Pavlov (19) demonstrated on dogs with a stomach pouch that 10% silver nitrate solution provoked the secretion of mucus in very large and at times enormous quantities.

Sollman (20) states that silver is not absorbed in sufficient quantity from the alimentary canal to produce systemic actions and that pills of ten to twenty milligrams of silver nitrate (made with kaolin and petrolatum) are sometimes used in gastric ulcer. As a gastric douche a solution of one-twentieth to one-tenth per cent silver nitrate followed by saline is given.

We desired to determine whether the beneficial effects reputed to have been obtained were due to change in gastric secretion. The gastric secretory response to a meal was studied before and after washing a Pavlov pouch with one: one-thousandth silver nitrate solution at two or three day intervals for one month (Table VIII). Frequent gastric lavage lowered the gastric acidity. It also increased the amount of mucus secreted, but we did not attempt to produce achlorhydria.

SODIUM SELENITE

We next attempted to produce experimental gastritis in a dog with sodium selenite, thinking that an anacidity might be produced without causing toxic symptoms. A dog's stomach was lavaged two or three times a week for six months with 50 c.c. 1% sodium selenite solution which was followed by lavage with water. Vomiting usually occurred after the lavage. Watery bowel movements occasionally occurred after vomiting, and frequently were positive for blood while the dog was on a meat-free diet. The amount of mucus in the gastric contents increased, and the secretory response to a meal and to histamine was markedly decreased, both in volume and in acidity, but achlorhydria was not produced. There was a garlic-like odor

TABLE VIII

The effect of silver nitrate lavage on the secretory response of the Pavlov pouch to a meal

of the breath. The red blood count, white blood count, hemoglobin and weight of the dog did not change (Table IX).

Another dog was given daily intravenous injections of 2 c.c. of a five-tenths per cent solution of sodium selenite as a control to determine whether the diminution in acidity was due to systemic or to local gastric effects. There was no reduction in the gastric secretory response of the stomach after one month of injections, and vomiting did not occur with this dosage. Vomiting did occur after intravenous injection of 4 e.c. of a one per cent solution, and vomiting occasionally occurred after 2 e.c. of a one per cent solution.

COBALT ACETATE

Twenty-five e.c. of cobalt acetate in six hundred c.c. of soya bean oil was administered by stomach tube daily for three and one-half months to two Pavlov

pouch dogs. Fifty-five experiments were performed on each dog during the administration of cobalt acetate, and thirty-one control determinations were made before cobalt administration. The secretory response to histamine was not appreciably influenced by the administration of cobalt acetate.

CONCLUSION

In the attempt to find a method of producing experimental achlorhydria, we studied the effects of a large variety of substances on the gastric secretion of man and dog. Although a diminution of acid secretion has been produced in some instances, no method that is practical for clinical use has yet been found.

We wish to express our appreciation to Miss Vivian Bass for her technical assistance.

Part of the expense of this investigation was defrayed by contribution from the E. L. Dawes Fund.

ALBERT E. SOBEL, Ch.E., M.A.

BROOKLYN, NEW YORK

IN previous communications (1, 2) from this laboratory a simple method of producing gastric lesions in the albino rat was described. It was shown in these experiments that pepsin in hydrochloric acid was far more effective than the acid alone in causing these lesions. The importance of pepsin has also been stressed by other investigators in recent years although in the past the hydrochloric acid received most of the experimental attention. Howes, Flood and Mullins (3) reported that operatively produced gastric defects in cats showed a greater delay in healing in the group receiving pepsin with acid, than those receiving acid alone. Clinical observations of Vanzant,

action has been summarized by Mann (6). He discusses the use of 1—dietary correction, 2—alkalinizing salts, 3—drugs, 4—emollients.

The present authors in their past investigations have emphasized that the continuous use of Bills' stock diet (8) for rats will prevent the onset of the lesions reported. A fasting period in addition to pepsin and hydrochloric acid was necessary for the experimental production of such damage to the stomach walls. It seemed desirable to carry these investigations further so as to establish that component of the diet which is responsible for this preventive action upon continued feeding. These investigations were carried out by ob-

TABLE I

All animals were fed Bills' stock diet with added fresh vegetables on the 1, 4, 7, 10, 13 and 16th days plus a continuous supply of 2% pepsin in 0.3% hydrochloric acid solution.	No. of rats	Added factor on fasting days (2, 3, 5, 6, 8, 9, 11, 12, 14 and 15th days)	Percentage weight loss	Incidence of lesions	Group incidence of lesions
	I. Control Group.				
	55	None.	—12%	55%	55%
	II. Protein Group.				
	10	Casein.	—26%	10%	10%

	4	Elastin.	Not estimated.	0%	
	4	Lean meat.	Not estimated.	0%	
	III. Carbohydrate Group.				
	24	Corn starch.	—20%	75%	70%
	10	Beta lactose.	—20%	60%	
	IV. Fat Group.				
	25	Butter.	—2%	88%	73%
	10	Lard.	—10%	50%	

Osterberg Alvarez and Rivers (4), confirmed by Mullins and Flood (5) seem to indicate that peptic ulcer in man is frequently accompanied by an increase of pepsin in the gastric juice.

The importance of the presence and composition of the acid gastric chyme in the formation of gastric ulcer has been stressed by a number of investigators. However, a more specific evaluation of the effect of the various components has been missing in these studies. The methods of preventing such corrosive

feeding the effect of feeding proteins, carbohydrates and fats to various groups of rats during the fasting period. This seemed of particular interest since the nutritional factor has been stressed by other investigators (7).

EXPERIMENTAL

The general plan of these investigations was to supply various factors on the fasting days. A total of 168 albino rats averaging three months in age were fasted two days and fed the Steenbock-Bills' stock diet (8) with added fresh lettuce or sliced carrots on the

*From the Department of Gastro-Enterology and the Pediatric Research Laboratory, Jewish Hospital of Brooklyn.

third day, in recurrent cycles, for a period of sixteen days. A 2% solution of pepsin prepared daily, (1:10,000 granular pepsin, Parke, Davis and Co.) in 0.3% hydrochloric acid was supplied to all the rats ad lib by means of stoppered flasks with glass tube outlets.

The above animals were divided into 4 groups as shown in Table I. The control group consisting of 55 animals received no dietary factor on the fasting days. The remaining 3 groups of 113 rats received a dietary factor on the so-called fasting days. The protein group (44 rats) received either casein, gelatin, elastin, or lean meats; the carbohydrate group (34 rats) either corn starch or beta lactose; the fat group (35 rats) butter or lard. These dietary factors were supplied ad lib. The average consumption per rat was about 5 grams daily.

The results are summarized in Table I. The lesions at autopsy were generally found to be multiple, with rounded margins and umbilicated centers. The gross and microscopic appearance of submucosal edema, cellular infiltration with varying degrees of desquamation and mucous membrane erosion were similar to that previously seen and described (1, 2, 9).

DISCUSSION

It is evident from the results of these experiments that proteins have a far greater protective power against the development of gastric lesions in the rat than either carbohydrates or fats. The incidence of lesions in the protein group was 10% in comparison with an incidence of 70% in the carbohydrate and 73% in the fat groups. Moreover the severity and the number of these lesions were small in the protein group in contrast to the carbohydrate and fat groups.

The mechanism of the protection afforded by the proteins is still problematic. There are in the main two general theories that may be presented. 1. Proteins supply a nutritional factor which increases the resistance of the stomach walls against the combined attack of pepsin and hydrochloric acid. 2. The digestive power of the pepsin is interfered with. The latter may be due to the "competitive retardation" of the products of peptic digestion of proteins or it may be caused by the acid combining properties of proteins.

The production of gastric ulcers on diets which were deficient in proteins were reported by several groups of workers. Pappenheimer and Larrimore (10) demonstrated that the gastric lesions in the rat were related to a deficiency in the diet. Hoelzel and Da Costa (11) produced gastric lesions in rats on low protein diets and found that alternate days of fasting increased the severity and the number of the lesions. They suggested a protein deficiency as a possible cause for these lesions. Wceh and Paige (12), while studying nutritional edema in dogs, found true peptic ulcers in a large percentage of their dogs maintained on a low protein diet. Howes and Vivier (13) produced gastric lesions in rats kept on a diet deficient in vitamins and proteins. These lesions were prevented by the feeding of yeast which is rich in proteins and the vitamin B complexes.

One of the explanations for the above behavior of low protein diets may be found in the amino acid deficiency theory of Weiss and Aaron (14). According to this hypothesis an insufficiency of certain essential amino acids would reduce the resistance of the tissues to a corrosive agent. These authors have cited, for

experimental evidence, the prevention of the gastric ulcers, following the Mann-Williamson operation in dogs, by the injection of histidine hydrochloride. However, this beneficial effect could not be confirmed by Sandweiss, Salzstein and Glazer (15) in their recent investigations. Moreover the senior authors of this paper (9) in their experiments found no preventive effects of histidine injections upon the production of gastric lesions in the rat. Thus the experimental support of the amino acid deficiency hypothesis is not sufficient at present. All of the experiments with protein deficient diets can be equally well explained by postulation of a positive inhibitory effect of the protein in the diet upon the activity of pepsin.

It is well known that the activity of certain enzymes may be stopped even when all other conditions are favorable, by the accumulation of the products of the reaction; and in certain circumstances, the action of the enzyme may be reversed so as to accelerate a change in the opposite direction to that in which it ordinarily acts. Wasteneys and Borsook (16) have carried out a very extended and systematic investigation of the reversion of peptic digestion. Thus proteins may very well prevent the further action of pepsin as they are digested due to the "competitive retardation" of the digestion products. Such an explanation may be offered for the inhibitory action of gastric mucin, chondroitin sulfuric acid and mucosin sulfuric acid (17, 18, 19, 20) as all of these can be isolated from the intermediary stages of protein hydrolysis.

Proteins may also inactivate pepsin in a different fashion. Due to the acid binding property of proteins a change in the pH of the medium can take place to such a degree that the optimum conditions for pepsin activity no longer exist. Thus 1 gram of gelatin or casein can combine with approximately 8.0 to 9.0 c.c. of 0.1 normal hydrochloric acid (21). The rats in our experiments have consumed an average of 5 grams of protein daily on the fasting days and they drink an average of about 8 c.c. of 0.1 normal hydrochloric acid daily (contained in the pepsin hydrochloric acid mixture). The pH of such a mixture would be about 3.8 to 4.0 in a test tube with gelatin as a protein. Since the optimum pH of pepsin is about 1.8 to 2.2 (depending upon the nature and the concentration of the substrate) such a change of hydrogen ion concentration will reduce the activity of pepsin to a small fraction of its optimal activity. Thus proteins can inactivate pepsin by their acid binding property.

While conceivable, it is unlikely that a nutritional deficiency of proteins played a part in the production of gastric ulcers in these experiments. This conclusion is based upon previous experiments (1, 2) where it was shown that animals maintained on Bills' stock diet with fasting and feeding cycles alone developed no lesions. On the other hand a second group on a similar regime but receiving pepsin in hydrochloric acid instead of water showed a 96% incidence of gastric lesions.

Weight loss seemed to play no part in the formation of the lesions. In the gelatin group, where the weight loss was the highest (—34%) the incidence of lesions was the lowest. In the butter group where the weight loss was the least (—2%), the incidence of lesions was 88%, and higher than in the control group. The high incidence in the butter group was also associated with

severe and more numerous lesions. Likewise in the experiments of Howes and Vivier (13), weight loss alone did not account for formation of lesions in their rats.

Thus the evidence is more in favor of protein acting as an inhibitory agent to the activity of pepsin. This may take place by either one or both of the inhibitory mechanisms previously discussed.

Whether this protective mechanism of proteins will be of value in the prevention and treatment of peptic ulcer in man will require careful clinical investigation.

It is hoped that the investigations which are in progress at present will elucidate more exactly the

mechanism by which proteins inhibit the formation of gastric lesions.

SUMMARY AND CONCLUSIONS

1. The relative importance of proteins, carbohydrates and fats in the prevention of ulcerative gastric lesions was investigated.

2. Proteins in the form of casein, gelatin, elastin and lean meat afforded a marked degree of prevention in contrast to the carbohydrate and fat groups.

3. The mechanism of this protection is ascribed to the interference of proteins with proteolytic activity of pepsin, which may be due to a "competitive retardation" of digestion products or the acid combining power of proteins or the combined effect of both actions.

Clinical Notes on the Use of Color Filters in Sigmoidoscopy

By

JOSEPH FELSEN, M.D.
NEW YORK, NEW YORK

THE purpose underlying the use of color filters in sigmoidoscopy is to render with greater clarity and detail structures otherwise scarcely visible to the eye. The principle involved is one commonly utilized in photomicrographic work in which a filter containing the complementary or contrasting color is interposed between the source of illumination and camera in order to give more "blackness" or contrast to structures which we wish to register on the photographic plate.

In sigmoidoscopic work we have found the green (type X, Wratten) and red (type A, No. 25, Wratten) most useful. Most of the pathological conditions encountered in sigmoidoscopy fall in the red range and are viewed with the green filter. Although the true complementary color is blue the filter is too dense for visibility. The green filter contains blue and transmits sufficient light from the sigmoidoscopic bulb. With the aid of the green filter punctate follicular lymphoid hyperplasia under the normal pink or inflamed

mucosa stands out clearly. The characteristic three stage pathology of acute bacillary dysentery (i.e. 1—punctate follicular hyperplasia; 2—punctate follicular necrosis; 3—discrete and confluent ulceration) can be followed with ease. The finer ramifications of the mesenteric arteries can be studied and will reveal a

Table showing applicability of the green and red filters in sigmoidoscopy

Green Filter:	Red Filter:
Arterial and periarterial lesions.	Hemorrhoidal veins and variceties.
Embolie lesions	Depth and character of ulcer edge.
Tumors.	Bluish pigmentation.
Lymphoid hyperplasia under inflamed mucosa.	
Outline and floor of ulcer.	

characteristic tortuosity in arteriosclerosis comparable with that seen in the retinal vessels of the same individual. With the aid of intermittent intestinal suction through the inflation tube of the sigmoidoscope their degree of patency and elasticity can be demonstrated. Embolic lesions in the smaller vessels are more common than thrombosis of a large mesenteric vessel in subacute bacterial endocarditis. The green filter makes the lesion stand out as a characteristic petechia with pale center. For the unpractised eye the sigmoidoscopic telescope will be found useful. Purpuric eruptions in purpura hemorrhagica, leukemia and agranulocytosis are visualized with greater clarity; also the outlines and floors of ulcers and smaller tumors such as the sessile adenomatous polyps, adenoma malignum, adenoma destruens or leiomyoma.

The red filter is used to study bluish to slate colored

pigmentation of the mucosa, hemorrhoidal veins and the depth and character of ulcer edges. In plumbism we have been able to demonstrate in three cases the presence of lead sulphide particles along the mesenteric arteries as well as a more diffuse bluish stippling of the intervening mucosa.

The practical application of these filters can be shown in a simple way by using colored sigmoidoscopic view plates such as are seen in Bensaud's or similar text book. During sigmoidoscopy we hold the filter between the light source and the eye. Since the filters are obtainable as colored gelatin sheets they may be fitted into the window of the sigmoidoscope or as two separate discs which may be swung in place as needed. It is preferable to obtain the gelatin strips cemented between two pieces of optical glass as specified above.

Continuous Drop Feeding for the Treatment of Ulcers of Stomach and Duodenum

By

A. L. SORESI, M.D.*
NEW YORK, NEW YORK

THE treatment of ulcers of the stomach and the duodenum must be based on the same principles which have been found successful in the treatment of ulcers of any other organ, with due consideration to the peculiar structure and function of the stomach and of the duodenum. Rest and prevention of irritation are the fundamental principles on which must be based and are actually based all successful treatments of ulcers, with the possible addition of disinfection, improvement of circulation, special medications, surgical procedures alone or combined.

The peculiar structure and function of the stomach and of the duodenum make it physically impossible to apply any of these means 100% efficaciously. In fact even if theoretically we should attempt to act as we do with limbs, that is abolish their function in order to obtain a perfect rest by casts, slings, special positions, etc., and consequently withdraw all solid or fluid foodstuff and beverages with the intention of putting the stomach and duodenum at rest, we know that rest would not be achieved. We all know more: the complete withdrawal of food and beverages would cause perhaps more activity of the stomach and of the duodenum and the ulcerated area would become more irritated by the undiluted acid secretions of the stomach.

Theoretically in order to achieve rest and prevent irritation we should completely withdraw beverages and food and at the same time stop the acid secretions of the stomach. Evidently we cannot do so. I shall not dwell on the limited efficiency of disinfectants, special medications, attempts to improve the circulation of the ulcerated area, etc.: consequently any form of treatment must be a compromise, the best being the best compromise. The treatment advocated in this

paper seems to be a practically successful compromise and conforms to our present knowledge of the digestive processes and of scientific therapeutics.

It is assumed that neither peristalsis nor acid secretions can be completely prevented: it is also assumed that disinfectants, special medications, means of improving the circulation around the ulcerated area or any other supposedly direct means of influencing the healing of the ulcer have proven rather disappointing. Consequently, the best compromise appears to be a method of proper feeding of the patient which will increase his stamina and resistance while reducing peristalsis, acid secretions, direct or indirect irritation and infection of the ulcerated area to a minimum. These desiderata seem to be realized by the following method: The patient is fed by the drop method day and night through a small rubber tube introduced through the wider nostril into the esophagus *not beyond the cardia*.

In this method three points are of fundamental importance: 1. The continuous day and night feeding by the drop method: 2. The special nutrient medium: 3. The position of the tube which should never be pushed beyond the cardia.

The continuous drop feeding prevents accumulation of the nutrient medium in the stomach, reduces acid secretions to the minimum and keeps them diluted to the maximum and affords complete feeding. The nutrient medium is based on milk, white of eggs mixed with water and gum acacia to which fruit juices and or special medications according to cases and indications may be added: the important point about the nutrient media is that they should supply the fluid, the calories and the vitamins required by each patient and be non irritant to the gastro-duodenal mucosa. The rubber tube should never be pushed beyond the cardia, because its presence in the stomach or duo-

*Visiting Surgeon, Greenpoint Hospital; Consulting Surgeon, Bushwick Hospital; Director, International Medical Center, New York.

denum constitutes a constant irritation of the whole organ and may irritate directly the ulcerated area. I insist on this point, because no matter how soft the rubber tube may be at best it must tickle the gastric or and duodenal mucosa, when it does not cause true irritation or direct pressure on some point. All living tissues will react to the presence of foreign bodies, the gastro-intestinal tract being no exception to this rule, reacts by increased peristalsis and secretion. The esophagus seems not to react to the presence of this small soft rubber tube practically hanging in its middle and hardly touching its walls.

The continuous day and night drop feeding method has been used for many years as the almost ideal feeding method for patients who had to be operated on the stomach, duodenum and occasionally on the biliary tract. Being a surgeon practically only advanced chronic cases are referred to me and for this reason my experience in the treatment of early ulcers of the stomach and duodenum has been limited. However, lately many colleagues have referred to me cases for diagnosis with my special X-ray apparatus and thus I had the opportunity to observe several early cases in close succession and treat them with very encouraging results.

The matter of the nutrient media requires still a great deal of consideration and study. In one case of bleeding ulcer, strong tea and milk were very effectual

in stopping the bleeding while supplying sufficient fluid and nourishment. The matter of medication requires also a great deal of consideration: atropine to reduce spasticity, morphine, pantopan, etc., to allow restful sleep or reduce excessive nervousness: strychnin, arseniate of iron, blood transfusion, complete rest in bed to bolster up a rundown organism have been used in connection with the continuous day and night drop feeding method. When to stop the drop feeding and resume normal feeding may be determined by X-rays and the general condition. The average amount of fluid nutrient medium has been 3,000 c.c. every twenty-four hours: it may be increased or decreased according to cases bearing in mind that it is absolutely indispensable to prevent accumulation of fluid in the stomach.

Although all the phases of this method of treatment have not been thoroughly studied due to the limited number of cases treated the results have been so encouraging as to induce me to present it to the medical colleagues in the hope of obtaining their cooperation in making it as efficacious as possible.

In connection with this subject I am happy to mention and give due credit to the pioneer works of Dr. Max Einhorn on duodenal feeding; the contribution of Dr. Rowland on intragastric drip, and Dr. Asher Winkelstein on continuous alkalized milk drip into stomach for therapy of peptic ulcer.

The Follicular Lesions of Vitamine A and C Deficiencies: A Critical Survey

By

HARRY KEIL, M.D.*
NEW YORK, NEW YORK

THE cutaneous manifestations observed in various forms of avitaminosis have received considerable attention in recent years. Especially is this true of the primary follicular lesions encountered in vitamine A deficiency, where they occur as part of a generalized epithelial keratinizing process (Frazier and Hu (1), Loewenthal (2) and others). The pilo-sebaceous apparatus may, however, also be affected in scurvy, such alterations being less intense and apparently secondary in nature. In a previous publication (Scheer and Keil (3)) two instances of scurvy in adults were recorded for the purpose of providing data on skin lesions of this sort. In one example, the follicular papules were somewhat similar to those seen in vitamine A deficiency: it was, however, noted that the patient had adopted a much restricted dietary regimen for several years and that, as a consequence, the possibility of simultaneous lack of the fat-soluble factor could not be eliminated entirely. This view seemed reasonable, considering the frequent occurrence of multiple vitamine deprivations, though the ordinary substantiating evidence, such as night blindness (hemeralopia) was lacking. In the second case, however, the superimposition of a hemorrhagic component provided a fundamental feature differentiating the follicular lesions of scurvy from those of vitamine A deficiency. In further support of this thesis, there

will be cited two additional cases of scurvy in which characteristic perifollicular petechiae were encountered as well as several other phenomena worthy of description. In concluding the paper an attempt will be made to set forth evidence indicating the essential differences between these two types of follicular eruptions, the recognition of which may aid in the detection of early cases of avitaminosis or hypovitaminosis.

Case 1. The patient was a woman, aged 29, who was observed for a period of about 6 weeks during the latter part of 1934. About 16 months before observation she complained of moderately severe diarrhea, characterized by the passage of from 3 to 5 stools daily; these contained mucus but no blood. She was placed on a diet consisting of egg-nogs, malted milk, toast, chicken soup, and small amounts of butter and orange juice. Vegetables, fruit, meat, and fish were excluded. On this regimen the diarrhea improved temporarily. About 4 months later there was an exacerbation of this complaint, as a result of which the dietary restrictions were enforced more rigorously. Shortly after, the fear of precipitating another attack of diarrhea caused the patient to restrict the intake of foods even more; orange juice was discontinued and she now subsisted largely on cereals, soups, and some boiled milk. A mild recurrence of the complaint led her to seek hospitalization; on this occasion proctoscopic examination revealed several ulcerations in the rectum and a barium enema showed incompetence of the ileo-caecal valve with spasticity and loss of haustrations in the colon.

*Adjunct Dermatologist, Beth David Hospital, New York City.

Fig. 1. Perifollicular petechial eruption of scurvy; each hair follicle shows a central cornified mass of moderate extent, with delicate deformed hairs, surrounded by a tiny zone of hemorrhage. Photograph taken several days after institution of vitamine C therapy when the hemorrhages were beginning to resorb.

Although no special efforts were made to treat the condition, the diarrhea ceased spontaneously and she was discharged as a case of ulcerative colitis. Several months later she began to complain of weakness and debility, the symptoms being aggravated by an upper respiratory infection of several weeks' duration. About two months before observation she experienced pains in the bones and joints, followed within a short time by the occurrence of tender gums that bled on the slightest trauma. The patient also noticed the appearance of small lumps in the skin, particularly on the lower extremities, the lesions rapidly assuming a hemorrhagic aspect. At about this time, larger black and blue spots were noted on the thighs. The left ankle became swollen and painful, the skin overlying the affected articulation showing a deep purplish discoloration. She complained of moderate cough. Three days before observation the patient felt feverish; the temperature rose sharply to 103° F. During the entire illness she had lost about 50 pounds in weight. There was no history of night-blindness.

On physical examination the patient appeared pale and emaciated. She was dyspneic, and she coughed. The teeth were covered with sordes. The alveolar margin of the gums, on the internal as well as the external aspect, was bright red, spongy, and bled easily. The edentulous spaces were apparently spared. The tonsillar remnants were ecchymotic. There was general dryness of the skin. In addition, the skin of the abdomen, arms, and lower extremities revealed definite hyperkeratosis of the hair follicles, with numerous delicate deformed curly hairs; there were occasional areas where the hairs were wanting. On the lower extremities where the eruption was characteristic, each lesion was surrounded by a zone of erythema or frank hemorrhage, according as the petechia was in the process of formation or in the stage of advanced development (Fig. 1). Here also, there were numerous delicate deformed hairs, many of which were curled up on themselves. There was evidence of old ecchymoses about the thighs, calves, and along the tibias. A large fresh ecchymosis with marked edema of the area was noted about the region of the left tendo achilles. There were physical signs of a pneumonic process in the left chest and, probably also, of atelectasis of the lower lobe of the left lung.

The hemoglobin was 38 per cent; the red cell count 2,810,000. The white cell count was 5800 with 71 per cent polymorphonuclear leucocytes. The tourniquet test was markedly positive, causing a fine spray of numerous hemorrhagic puncta in the fold of the elbow. The bleeding time, coagulation time, and platelet count were normal. The temperature ranged between 103.8° F. and 104.4° F. Because of the marked anemia, she received a blood transfusion. Orange juice (500 c.c.) was given immediately and, by the following morning, the general condition of

the patient was eminently improved, contrasting with the precarious state on initial observation. Within 24 hours the gums were less red and spongy. During the succeeding nine days crystalline cevitamic acid, 3 grains daily, was administered by mouth; tomato juice, orange and other fruit juices were eliminated from the diet. Improvement continued unabated and, within the next few days, the condition of the gums improved considerably and the skin lesions (ecchymoses and perifollicular petechiae) began to undergo rapid involution. Within a period of from one week to 10 days, the texture of the skin became almost normal, although the faint brownish spots marking the situation of the perifollicular hemorrhages, required about a month for complete disappearance. The patient gained weight steadily and the abnormal physical signs in the left lung cleared up completely, with the exception of slight dullness at the base, attributed to the presence of thickened pleura. The tourniquet test became negative about 10 days after the institution of vitamin C therapy.

Comment: From the clinical point of view the case was a typical one of scurvy, apparently uncomplicated by any other vitamine deficiency. There were no symptoms referable to deprivation of fat-soluble factor, such as night-blindness. The association of broad areas of ecchymoses, spongy bleeding gums, and perifollicular petechiae constitutes a triad of signs commonly observed in adult scurvy. The immediate response to orange juice and the unabated improvement under cevitamic acid was striking, contrasting with the slower course seen in patients recovering from vitamine A deficiency; this point will be elaborated upon in a subsequent section. The general dryness of the skin was probably caused, for the most part, by loss of fluid through diarrhea, aided perhaps by fever; this sign was not noted in the next case in which gastro-intestinal symptoms were lacking.

Case 2. This patient was a woman, aged 44, who complained of pain about the ankles and swollen bleeding gums of 6 months' duration. About 18 years before the present observation she had an operation for ectopic pregnancy. Shortly after, she experienced nausea and epigastric distress, causing her to limit intake of foods to such a degree that, during the past 10 years, she had subsisted almost entirely on cereals, eggs, bread and coffee. Fresh vegetables and fruits were completely eliminated from the dietary regimen; indeed, the distaste for fruits became so intense that the mere sight of them caused distress. Eight months before observation she learned that she had high blood pressure, for the alleviation of which eggs were eliminated. In the past few weeks the diet had, therefore, consisted of but cereals, coffee, and cream, and bread. About six months before that, the gums became

Fig. 2. Scorbutic hemorrhage into the inferior angle of a scar on the abdomen; slight hemorrhage also in the upper angle.

swollen, tender to touch, and bled on the slightest trauma. At the same time she noted pains in the lower portions of the tibiae and about the ankles, the skin overlying these parts becoming swollen and ecchymotic.

Physical examination showed a thin, poorly nourished woman whose skin was not particularly dry. The gums were turgid, colored purplish red, friable, spongy, and bled easily. There was a large ecchymotic area about the left ankle. Over both legs and over the lower portions of the thighs, there were pinhead perifollicular petechiae characteristic of those encountered in scurvy. As in the first case, the centers showed moderate degree of hyperkeratosis, with many scattered curled delicate hairs arising in each follicle. Similar lesions were seen on the lower part of the back. A remarkable feature was the presence of a large area of hemorrhage situated mainly in the inferior angle of an operative scar located on the abdomen (Fig. 2). The tibiae and ankles were tender and mobility was limited owing to pain.

The hemoglobin was 72 per cent; the red blood cell count 4,100,000. The platelets numbered 250,000. The tourniquet test was markedly positive; the bleeding time, coagulation time, and clot retraction were normal. Examination of urine specimens revealed no abnormal findings. There was no evidence of bleeding from the gastro-intestinal tract (gastric contents and specimens of stool). Roentgenologic examination of the chest (heart and lungs) disclosed no abnormalities; in addition, there was no evidence of subperiosteal elevation of the bones of the lower extremities. Despite the previous dietary restrictions, there was no diminution in blood protein (6.6 mgs. per cent). The blood pressure was 180 systolic, 100 diastolic.

The patient was given liberal quantities of orange juice and a soft diet rich in vitamins. The improvement was dramatic; the swollen gums diminished in size and turgor, bleeding ceased, and the tenderness disappeared; the

ecchymoses and follicular hemorrhages underwent rapid involution, the original sites of the latter lesions being marked by the presence of tiny pigmented spots centered by a hair in most instances; the tourniquet test now became negative. The appetite improved and she no longer experienced the feeling of distaste for raw fruits and vegetables.

Comment: The perifollicular petechiae encountered in this case were the precise counterpart of those seen in the first patient. The clinical course and response to ingestion of orange juice were also identical. A remarkable feature was the presence of an area of hemorrhage in a scar situated on the abdomen, and it is probable that the bleeding was subcutaneous in type with infiltration of the upper layers of skin. As in the first case there was no clinical evidence pointing towards deprivation of the fat-soluble factor; in addition, the diet, though markedly restricted, had contained cream which is an excellent source of vitamine A.

FOLLICULAR LESIONS OF SCURVY

(a) *Introductory General Remarks:* The pilo-sebaceous apparatus is a structure supplied by a rich plexus of capillaries. It appears that this system is not established in its definitive form until the age of 4 or 5 years, only to be influenced profoundly at puberty (Frazier and Hu (1b)). It is probable that nutrition of this structure is accomplished through the blood and lymph channels (tissue spaces), although present knowledge of the precise mechanism is fragmentary. Disease of the hair follicles may be a primary process when the epithelium is initially involved or the changes may be secondary in nature when, for example, there is a defective blood supply or interference with that portion of the circulation. In many instances this distinction cannot be clearly established. In the case of vitamine C deficiency, there is evidence that disturbances in the blood vessels constitute the primary causative factor and that hyperkeratosis of the hair follicles and other changes (curling, thinning, and temporary loss of hair) are of secondary origin. It has been shown (Aschoff and Koch (4), Wolbach and Howe (5)) that the fundamental defect in scurvy appears to be the inability of the supporting tissues "to produce and maintain intercellular substance." By implication based on thorough general pathologic studies, Aschoff and Koch suggested that the hemorrhagic manifestations of vitamine C deficiency are caused by an impairment of the intercellular substance supporting the blood vessels. According to this view, then, the endothelium of capillaries is unable to form the normal cement substance allowing for diapedesis of red blood cells and serum.

The distinguishing feature of the eruption seen in scurvy is the occurrence of tiny hemorrhages around the hair follicles, producing perifollicular petechiae. So far as the superficial vessels of the skin are concerned, maximal capillary fragility seems to be confined, for the most part, to the blood channels supplying the pilo-sebaceous apparatus. In some cases this can be shown experimentally in humans by means of the tourniquet test (Korbsch (6)). In one instance, for example, the application of a tourniquet about the right arm produced numerous tiny hemorrhages confined principally to the areas about the hair follicles on the forearm (Scheer and Keil (3)). In other

patients, however, this procedure gives rise to innumerable hemorrhagic puncta, apparently independent of the follicular openings; it may be agreed, therefore, that other vessels of the superficial skin may apparently also be affected.

Perifollicular hemorrhages are likely to be more intense and to be encountered with greater frequency in areas of the body where the pilo-sebaceous apparatus is more highly developed and in races where the hairy system is more pronounced (Salle and Rosenberg (7)); indeed, unusual variations in situation of these patches may frequently be correlated with abnormal distribution of hair. There may, however, be occasional exceptions to these rules. It is probable that these factors likewise influence distribution and intensity of the process seen in the follicular eruption of vitamine A deficiency.

The clinical phenomena of scurvy (bleeding gums, massive hemorrhages about the muscles and subcutaneous tissues, the hemorrhagic phenomena produced in the more superficial areas of skin, the positive tourniquet test, etc.) constitute evidence of the predominant part played by vascular disturbances in the symptomatology. When the missing vitamine is replaced in the diet, these manifestations disappear rapidly as a rule.

(b) *Clinical Features of the Skin Lesions:* In its well-established form the perifollicular petechial eruption appears to be pathognomonic of scurvy. As far back as 1871, Lasèque and Legroux (8) recognized its diagnostic importance as an early sign of the disease. Of 75 cases of the condition seen by Salle and Rosenberg (7) in 1917, 10 showed this manifestation as the presenting sign. During the World War when the opportunities to study the disease on an extensive scale were ample, numerous observers stressed the clinical significance of these skin lesions (Feig (9), Pfeiffer (10), Arneth (11), Wiltshire (12) and Korbach (6) among others). Of the 4 cases of this disease observed by me in civilians, 3 of them presented the dermatosis in its typical morphology. In the remaining instance it was differentiated with difficulty from the somewhat similar eruption of vitamine A deficiency, and the view was therefore expressed that the initial follicular lesions of scurvy may sometimes clinically resemble those seen in patients suffering from deprivation of the fat-soluble factor. This difficulty, however, arises only in occasional instances, as will be shown in a consideration of the fundamental attributes of both eruptions. In two cases of scurvy in infants the follicular hemorrhagic dermatosis was not encountered; this manifestation is but rarely mentioned in pediatric texts and monographs. The characteristic skin lesions are, therefore, met with most frequently after the age of puberty.

The eruption manifests particular favor for the extensor aspects of the lower extremities (legs, anterior and inner parts of thighs) and of the upper limbs (forearms, occasionally the arms). It is also seen on the lower part of the abdomen, and occasionally in advanced cases, on the chest. Hair-free portions of the body and areas with a poorly developed pilar system usually remain unaffected (popliteal spaces and elbows) (Salle and Rosenberg). The face, scalp, hands, and feet appear to be spared. It is found in its most typical form on the legs where practically

every hair follicle may be involved by the hemorrhagic process. It is not unusual to see perifollicular petechiae at sites of predilection, whereas less favored areas, like the abdomen, may reveal simple hyperkeratosis at the mouths of follicles, with an occasional surrounding hemorrhage. In the latter situation the individual lesion may resemble that seen in vitamine A deficiency; unlike the latter condition where keratosis is usually a pronounced feature, often leading to secondary phenomena (pressure atrophy), the accumulation of hyperkeratotic masses is moderate in intensity.

When the hand is passed over the affected areas in scurvy, the impression of a nutmeg grater is produced and the older clinicians (Jessner (13)) spoke of the phenomenon as "lichen scorbuticus" or "scorbutic goose-flesh." This attribute is, however, not pathognomonic of any single skin ailment; it merely describes the sensation imparted to the palpating hand by hyperkeratotic accumulations as encountered in many cutaneous conditions (lichen pilaris, pityriasis rubra pilaris, follicular ichthyosis, follicular papules of vitamine A deficiency, etc.). In scurvy, therefore, involvement of the follicular apparatus also occurs, but it is secondary in type and less intense than in the case of vitamine A deficiency. It is less likely to cause "atrophic depressions" by pressure of hyperkeratotic masses; for example, gaping cavities are not seen when the central plugs are removed, as in the skin lesions attributed to lack of the fat-soluble factor.

The eruption of scurvy appears to have the following course. The initial disturbances in the peripilar capillaries cause nutritional alterations in the follicular apparatus, leading to hyperkeratosis as well as curling and thinning of the hair. In this early stage, and especially in certain locations (abdomen), gross hemorrhage may not be apparent clinically, although it is probable that mild degrees of interstitial extravasation of blood could be demonstrated on histologic examination. The usual onset is in the form of bright red puncta about hair follicles; these may be scattered at first, then cover an entire limb. As the lesions increase in size, they become bluish red, forming lichenoid papules owing to the central projection of hyperkeratotic material, aided in some cases by the transudation of serum. In its fully developed stage the lesions vary in size between that of a pinhead to that of a split pea in occasional instances. Subjective symptoms attributable to the dermatosis are uncommon, itching being a rare complaint. In its later course the hemorrhage is resorbed slowly, leaving pigmented spots (hemosiderin) for months. The centrally situated hairs may be broken off, at times may have fallen out. If the deficient diet is maintained, the eruption may remain in the same state for months. When adequate therapy is instituted, there takes place a dramatic restitution ad integrum, which will be described in a subsequent section.

As regards secondary infection, pustulation and scarring, observations differ relative to their incidence and significance. Arneth described large follicular petechiae, occasionally capped by central pustules which later dried without undergoing any other changes. It has been stated that furunculosis is a fairly frequent complication in such cases. Under these circumstances, scarring of some lesions may be

expected, but the phenomenon is uncommon and secondary in type. In agreement with Salle and Rosenberg, I am unable to confirm the high incidence of such secondary complications, notwithstanding the point that in several of the patients observed by me, the condition had been present for many years.

It has been stated that in the typical form described the eruption is pathognomonic of scurvy. The dermatosis is readily distinguished from the "hemorrhagic folliculitis" occasionally observed in Gaucher's disease (larger isolated lesions up to a dime in size, occurring on the inferior extremities, few in number, healing with the formation of large pigmented scars) and from a host of diseases producing skin eruptions with incidental, rare, isolated, and unimportant involvement of hair follicles as compared with the other features presented by the dermatosis (Henoch-Schönlein-Osler syndrome, uremia, acute lupus erythematosus, subacute bacterial endocarditis, varicose complex and many other affections). On the basis of the pathologic observation that both rheumatic fever and scurvy affect collagenous tissue throughout the body, it has been suggested by Rinehart (14, 15) and his co-workers that the former disease may be the result of the "combined influence of vitamin C deficiency and infection." It is not within the province of this paper to enter into a detailed discussion regarding the probability of this hypothesis, but it does seem pertinent to note that, although hemorrhagic phenomena occur in the course of rheumatic fever, they bear no clinical similarities to the lesions encountered in scurvy (Keil (16)).

(c) *Pathology*: The vascular alterations producing the typical morphologic attributes of the eruption constitute the one striking characteristic feature, the remaining changes in the epidermis appearing to be of banal type. In 1871, Laségue and Legroux, on the basis of a histologic study of these skin lesions, noted that the hemorrhagic extravasation was disposed principally about the hair follicles. In the detailed microscopic examinations practiced by Nicolau (17), swelling of the endothelial walls of the perifollicular capillaries was noted; the extravasation of red blood cells in isolated groups and in small numbers, without particular damage to surrounding tissues, was stressed by this observer who regarded this feature as evidence of diapedesis through the parietes of the affected vessels, an observation which is in essential agreement with the view relating to the inability of endothelial cells to form normal cement substance in this disease. Nicolau also found that in occasional instances there was transudation of serum in moderate amounts. In a previous paper (Scheer and Keil) there was appended a histologic report on an "erythematous" follicular papula that on gross examination showed but slight evidence of hemorrhage, although the remainder of the eruption, shortly after the initial appearance, became definitely hemorrhagic in type. Study of this relatively early lesion revealed the presence of interstitial extravasation of red blood cells, most conspicuous about the hair follicles, associated with transudation of serum which explained, for the most part, the gross elevation of the lesion. It was difficult to distinguish the outlines of the peri-

follicular capillaries owing to the swelling of the walls, about which there was a moderate infiltration of lymphocytes. That the pigment found in the tissues is derived from the blood was shown by Nicolau who obtained positive iron reactions; in advanced cases, therefore, the pigmentation is probably caused by the deposition of hemosiderin.

The epithelial changes seen in the case reported by Scheer and Keil were apparently secondary in type. The hyperkeratosis of the follicular orifices was moderate in extent, hardly rivaling the intensity of the process as seen in vitamin A deficiency. There was no resultant pressure on surrounding structures; hence, little likelihood of secondary pressure atrophy with the formation of gaping cavities on extrusion of the central keratotic material. In healing, therefore, conspicuous depressed areas marking the former sites of lesions are not to be expected, except rarely when there is superimposition of infection. The significance of the finding of hypertrophied arrectores pilorum muscle as described by Aschoff and Koch, Nicolau and others, is as yet unknown.

(d) *Therapeutic Response*: Until the advent of crystalline extracts of vitamins, it was most difficult to apply an absolute therapeutic test. For example, orange juice is said to contain not only vitamin C, but also vitamin A or its precursor carotene (Jeghers (18)) in amounts sufficient to cure rats suffering from xerophthalmia (Wolbach and Howe (19)). In a similar manner, Frazier and Hu (1a) treated their original series of cases of vitamin A deficiency by means of a balanced diet combined with cod liver oil and one lemon a day (vitamin C). There are, however, a few reports indicating that the therapy used was such as to warrant the drawing of accurate conclusions relative to the precise vitamin lack.

In the first case cited in this paper orange juice was given on the first day of observation, with striking amelioration of the symptoms. As the foodstuff also contains vitamin A or its precursor, it was interesting to note that rapid improvement continued with the oral administration of cevitic acid (crystalline vitamin C). Equally striking was the rapid involution of the perifollicular hemorrhages, practically complete resorption taking place in about 10 days, though faint brownish spots persisted for several weeks. The central keratotic plugs were extruded and towards the end of the period of observation of some 6 weeks many normal hairs seemed to be regrowing. At this time, the character of the skin could be designated as normal. The rapidity with which the skin lesions underwent involution in the cases observed by me would seem to contrast with the slower course recorded in most of the patients recovering from the effects of deprivation of vitamin A. Where the central keratotic plugs require many months for healing or leave depressed areas at the sites of hair follicles, in the absence of gross secondary infection, there may be reason to suspect coincidental lack of the fat-soluble factor, though the latter may in some cases be so slight in degree as to fail to cause obvious clinical symptoms. It is undoubtedly true that the simultaneous lack of both vitamins A and C occurs not infrequently, and it will be an interesting problem

to determine the relative part played by each in the evolution of the skin lesions observed in such instances.

Follicular Lesions in Vitamine A Deficiency:

(a) *General Concept of the Disease and General Clinical Data:* Deficiency in the fat-soluble factor gives rise to a systemic condition in which there occurs keratinizing metaplasia of the various epithelial-lined structures in the body (Wolbach and Howe (19) and others). The site of predilection are the eyes (night blindness, xerosis, Bitot's spots, pigmentation of the conjunctiva, keratomalacia) and the skin (generalized dryness, follicular lesions), but experimental evidence in animals (Wolbach and Howe, Goldblatt and Benischek (20)) and postmortem examinations in human beings (Wilson and DuBois (21), Blackfan and Wolbach (22), Thatcher (23), Sweet and K'Ang (24)) demonstrate that the process involves the internal organs as well, the principal alterations being the substitution of keratinizing epithelium causing occlusion of ducts and formation of cystic structures. There is some evidence, also, that there may be a direct effect on the secreting abilities of glands. In addition, it appears that pathologic changes suggestive of this condition may be observed postmortem in the absence of the usual clinical features of the disease (Blackfan and Wolbach) and many investigators are now concerning themselves with the sub-clinical phases of the condition (Jeghers (18)), which is supposed to be more common than has been generally suspected. The relation of vitamine A to the formation of rhodospin (visual purple) found in the retinal rods seems well established (Fridericia and Holm (25) among others); and as the rods are most numerous in the peripheral fields of the eyes which are concerned with vision at night, deprivation of the fat-soluble factor leads to a lessened adaptation to diminished light (Chou (26), Jeghers (18)). It also seems to be established that carotene is a precursor of vitamine A and that the conversion takes place under the influence of the liver where the vitamine is chiefly stored. In adults the larger reserves of the fat-soluble factor and the lesser requirements for growth are factors that may account for the lower incidence of the severer forms of the disease; most of the cases observed in the older age-group have been reported in peoples (for example, the Chinese) whose dietary habits are such as to preclude any intake of vitamine A or to restrict ingestion to minimal amounts of it.

The general dryness of the skin, attributed by some to dehydration, undernutrition or intercurrent disease, may be dependent, in part at least, on the specific effect arising from vitamine A deficiency (epithelial, sebaceous gland, sweat gland changes, singly or combined). This symptom, usually encountered early in the disease, is generally the only cutaneous disturbance seen in children. Commonly associated with it is the absence of visible sweating, probably caused by alterations in the sweat glands proper or in their ducts. In advanced form these changes in the skin are considered to be factors in causing the peculiar febrile attacks commonly encountered in the condition, though Sweet and K'Ang (24) believe that a better explanation lies either in the absorption of toxins through altered epithelium or in the metabolic changes that

may ensue from more rapid utilization of fat by the body in an attempt to obtain the fat-soluble factor. In some of the late cases the hair of the scalp is found to be dry, coarse, brittle, manifesting a tendency to fall out; the nails may reveal transverse or longitudinal furrows and are lusterless (Pillat (27)). All the alterations noted respond to the ingestion of vitamine A, provided the changes are not too far advanced (Wilson and Dubois (21), Ross (28)) or there is no severe diarrhea preventing the utilization of the factor, or there is no marked impairment in liver function interfering with the storage of vitamine A and the conversion of carotene into it. These points must be taken into account in evaluating the therapeutic response to ingestion of the fat-soluble factor.

It is believed by most observers that the ocular symptoms constitute the initial manifestations of the disease. There is evidence indicating variability in this general rule. From the clinical point of view Frazier and Hu noted that skin lesions may appear *before the onset of obvious ocular changes*. The close relation between these organs and the analogies between them are illustrated by the alterations in the eyes; the conjunctival epithelium, for example, takes on the character of true skin. There is an increase in its thickness owing to the formation of corneous material and conspicuous kerato-hyaline layer. In adults, moreover, pigmentation occurs in the majority of cases (Mori (29), Pillat and King (30)), attributed to the presence of melanoblasts in the basal layer, and it appears that this phenomenon may have its counterpart in the skin.

Patients afflicted with vitamine A deficiency are considered to be prone to infection only in so far as the changed character of the various epithelial-lined structures of the body may be associated with inability to withstand multiplication of bacteria. The disease may become severe enough to result in death, the most common cause being "bronchopneumonia" secondary to pathologic alterations in the smaller radicles of the respiratory tract.

(b) *Clinical Features of the Follicular Eruption of Vitamine A Deficiency:* It is interesting to note that in 1908, Little (31), on the basis of his experience among the Eskimos, described an endemic of pustular dermatitis or Kallak which resembled scabies owing to the location and manner of spread of the skin lesions coupled with the intense itching; it differed, however, in many clinical particulars, among which may be mentioned failure to respond to sulphur therapy and, on the other hand, cure following the establishment of a relatively normal diet. The condition occurred after the patients had lived exclusively on fish, and notably in conjunction with failure of the berry crop. As suppurative processes are especially common among the Eskimos, the eruption probably represented the result of dietary insufficiency and superimposed infection. The disease did not spread to foreigners who came in contact with the Eskimo, but whose dietary regimen differed. In 1917, Little (32), attributed the condition called Kallak to lack of the fat-soluble factor, the deficiency occurring when the fats derived principally from the seal and the caribou, could not be properly utilized. He also mentioned the case of a shipwrecked white man who came down with the disease in severe form after adopting the re-

stricted dietary regimen of the Eskimos. Among others who have concerned themselves with the cutaneous manifestations of vitamin A deficiency are Stannus (33), Pillat (27), Mackay (34), Nicholls (37) and Goodwin (35). The cases described by Nicolau (17) (1918-19) and the report issued subsequently by his pupil Theodorescu (36) (1928) will receive separate consideration. The outstanding accounts of the peculiar follicular lesions seen in this disease are those of Frazier and Hu (1) (1931, 1936) and Loewenthal (2) (1933), whose clinico-pathologic descriptions have been utilized in this report.

As in scurvy, the dermatosis observed in vitamin A deficiency occurs particularly on the extensor aspects of the upper and lower limbs, to a lesser extent on the abdomen, chest, loins, and buttocks. The face and neck are often involved, especially when the eruption is generalized over the body; the importance of this feature will be discussed in a succeeding paragraph. With the exception of these latter areas, the sites generally spared in vitamin A deficiency are essentially the same as those avoided in scurvy. The eruption may appear rather suddenly and extend rapidly over the areas of predilection. According to Frazier and Hu, it may antedate the occurrence of obvious ocular signs by as long a period as 5 months. The follicular dermatosis is encountered most frequently in adults; in children the cutaneous changes appear to be restricted to general dryness, the explanation for this difference in clinical behavior probably lying in the incomplete state of development of the pilo-sebaceous apparatus in the younger age-group.

The typical lesion is the follicular papule, characterized by the occurrence of marked hyperkeratosis of the hair follicle openings. It varies in size from that of a pinhead to that of a lentil in occasional instances. In many cases there is lack of an accompanying inflammatory element; in other examples superimposed evidence of inflammation is present, though relatively mild in degree. The hyperkeratosis presents itself as a dry, firm, intrafollicular plug which may occasionally project in the form of a spine or it may be covered by loosely adherent scales (Frazier and Hu). When the hand is passed over the affected areas, there is created the impression of "highly accentuated" goose flesh. Expressing the plugs frequently discloses gaping cavities, another indication of the pronounced degree of hyperkeratosis. The immediately surrounding perifollicular zones are often pigmented as a probable consequence of increased melanin pigment in the basal layer of the skin; this phenomenon has its probable counterpart in the conjunctivae of adults afflicted with the disease. The discoloration is, therefore, not caused by the deposition of hemosiderin from extravasations of blood. As in scurvy, but to a greater degree, the hairs in the affected follicles are broken, deformed, or have completely fallen out. It is probable that in many cases these are not replaced owing to the advanced degree of interference with growth, occasioned by pressure atrophy. Itching appears to be variable in incidence and intensity; it was absent or minimal in the cases reported by Frazier and Hu and fairly constant in the patients observed by Loewenthal. Frequently there is associated absence of visible sweating of the skin, a feature of great importance in the evaluation of the effects of specific therapy.

The lesions which are met with on the face are of special importance. Owing to the formation of numerous large "comedones," acne vulgaris is simulated. Unlike the condition in ordinary cases of acne vulgaris, the skin of the face is generally dry (Frazier and Hu (1b)), though exceptions have been recorded by Loewenthal (2); there is little tendency for pustule formation as judged by gross inspection; the cases occur in people beyond the acne age; and the sites of predilection are areas of the body spared in ordinary acne. On morphologic grounds there may be some resemblance to tar or oil acne, which are, however, distinguished by a history of contact with these substances. Bromide and iodide acne show a greater tendency to affect the face and chest than is generally seen in vitamin A deficiency, and the lesions are usually of the inflammatory pustular type. In the accounts of the hemorrhagic follicular dermatosis observed in scurvy, involvement of the face and neck has, thus far, not been recorded, even when the lesions were otherwise widely distributed. Implication of the dorsum of the hands and of the feet, as reported in one unusual instance of vitamin deficiency (Frazier and Hu (1b)), has not been seen in scurvy. The localization of numerous typical hyperkeratotic lesions on the posterior aspects of the elbows is frequently observed in vitamin A deficiency, rarely in scurvy.

In their further development the lesions of vitamin A deficiency, which may persist for months, often undergo involution, with the production of definite depressed atrophic areas surrounded by a narrow zone of pigmentation. These healed areas, probably occurring in the absence of gross secondary infection, may be seen interspersed in small numbers among numerous lesions of more recent origin. It is important to stress that at no time during the course of the eruption is a hemorrhagic component seen as in scurvy.

Regarding the importance of the element of infection, there is much diversity of opinion. It seems to be generally accepted that this may occur secondarily late in the course of the disease and that it is attributable to changes in the epithelium allowing multiplication of bacteria. According to Spense and Mackay, there is a high incidence of "skin sepsis" in vitamin A deficiency as manifested by the association of impetigo, boils, diaper rashes, etc. These observations were made in infants and children and are in need of further confirmation from other sources. On the other hand, there are observers who have not been impressed by the incidence of such complications in this disease (Blackfan and Wolbach (22), Sweet and K'Ang (24)). So far as the follicular lesions are concerned, it seems to be agreed that gross secondary infection of them is rare (Loewenthal) or only present in occasional instances, particularly when there is general undernourishment (Frazier and Hu). When this complication occurs, scars are produced; in occasional instances large ulcerations may result (called dermalacia by Pillat who tried to correlate the phenomenon with keratomalacia), and these lesions may rarely simulate secondary ulcerative syphilids (Frazier and Hu). It is possible that in occasional cases the epithelium of the hair follicles may proliferate to form outpocketings or small communicating pouches that contain collections of pus, but such lesions are relatively uncommon and do not necessarily break down to form ulcers, spontaneous resorption occurring.

Relative to specificity of the follicular lesions seen in vitamine A deficiency, there seems to be excellent evidence, both theoretical and practical, that the eruption is attributable to lack of the fat-soluble factor (Loewenthal, Frazier and Hu). That, however, all such lesions represent the manifestation of lack of this factor, as has been maintained by Frazier and Hu (1b), is a proposal with which there may be some disagreement. Nevertheless, their point is well taken when they question the diagnosis of the case recorded by Theodorescu (36); the occurrence of hemeralopia, followed in two weeks by the appearance of a generalized eruption implicating the face and neck as well other parts; the presence of many small pigmented scars or depressions; the absence of a hemorrhagic component despite the widespread distribution of the dermatosis; the occurrence of numerous "comedones" on the face; the marked epithelial changes on histologic examination coupled with the lack of pronounced alterations in the perifollicular capillaries; the healing of lesions with the formation of pigmented depressed areas are points that appear to argue for the inclusion of the case within the category of vitamine A deficiency, even though there was simultaneous evidence of scurvy in the patient. On the other hand, I am unable to accept in its entirety the interpretation offered by Frazier and Hu that the dermatosis described by Nicolau (17) can only be attributed to vitamine A deficiency. It is true that in the second case recorded by this observer, the patient had hemeralopia, but it is equally true that there was unmistakable evidence of scurvy. It seems more probable, in view of certain atypical features, that there was simultaneous deprivation of both vitamins A and C, though it is my belief that the clinical picture was dominated by manifestations of scurvy. It seems interesting to analyze the basis for this belief, as this question will persistently arise whenever there are multiple deficiencies. The evidence favoring the view relating to lack of vitamine C are the typical clinical symptoms of scurvy; the occurrence of perifollicular petechiae; the failure to involve the face, neck, and scalp in all 40 cases seen by Nicolau, even when the rash was widespread in distribution; the pathologic alterations in the blood vessels allowing diapedesis of red blood cells; the rapid absorption of hemorrhages; and, finally, the healing of lesions without the formation of depressed areas at sites of hair follicles. The atypical features pointing towards superimposed lack of vitamine A are the occurrence of hemeralopia; the relatively greater degree of follicular hyperkeratosis; the presence of epithelial hyperplasia with the formation of outpocketings and small communicating channels in the hair follicles; and the long time required for healing of the keratotic accumulations that remained long after the hemorrhagic manifestations had disappeared. It will be seen, then, that the case recorded by Theodorescu from the same clinic nine years later differed in many clinical and pathologic particulars from the observations originally reported by Nicolau (17). The association of vitamins A and C deficiencies is probably not uncommon, judging from the frequent description of hemeralopia in epidemics of scurvy. It will be of great interest to ascertain the part played by each condition in the evolution and the clinical attributes shown by the follicular eruption, whether or not hemorrhage is present. It is likely that

in some instances it will be impossible to differentiate these dermatoses without observing them for long periods and without the aid of histologic examination, and the difficulties will be the greater as both conditions are combined in varying proportions.

(c) *Pathology*: The outstanding features are those concerned with the epithelium of the hair follicles. Within these structures are found dense masses of cornified cells, occasionally containing the remains of coiled atrophic hairs (Frazier and Hu). The epithelium adjacent to the follicles, and, even at some distance from them, shows evidence of hyperplasia, causing elongation of the rete pegs. As a result of the intense cornification, pressure is probably exerted on the lower parts of the follicles, resulting in atrophy and, probably also, disappearance of sebaceous glands, with replacement by infiltration of lymphocytes. It is interesting that giant cells have not been encountered thus far. Frazier and Hu also recognized a similar obstructing process in the upper parts of the sweat ducts, especially that portion lying within the epidermis; they also noted some degenerative changes in the oil glands proper. In one instance a cyst filled with cornified material was found near a hair follicle. In none of the sections was hemorrhage seen, nor was there evidence of diapedesis of red blood cells; in this respect there is a fundamental difference from the alterations found in scurvy. It is my belief that the depressed areas seen after healing takes place are the result of pressure atrophy occasioned by the dense masses of keratinized material formed in most of the hair follicles in this disease and that this occurs, according to most descriptions, in the absence of frank infection. Collections of pus cells may infrequently be noted in the wall and lumen of the hair follicles and any outpocketings formed by proliferation of epithelium; they may be resorbed spontaneously or be the background for the larger ulcerative lesions occasionally noted in the course of the disease. It has been stated by Loewenthal (2) that the striking blackness of the papule may be the result of a relative increase of melanin pigment per square unit of surface, attributed to the acanthosis and wrinkling of the upper layers of the epidermis; this observer found no increase in the number of dermal chromatophores. It appears, therefore, that the pigmentation seen about such lesions is more prominent clinically and that it is a phenomenon requiring further pathologic investigation.

(d) *Response to Therapy*: The difficulties encountered in submitting patients to a critical therapeutic test as regards specific vitamins have been noted by Frazier and Hu; in treating their original group of cases, a diet rich in all the accessory factors was used. However, by a process of elimination it was shown by Loewenthal (2), with a reasonable degree of certainty, that the missing element in these cases was vitamine A or some fat-soluble factor. Treatment with cod liver oil without changing the remainder of the diet resulted in the disappearance of the follicular lesions in practically all of the 74 patients after a period of some nine weeks. In a critical experiment in two instances Loewenthal was able to eliminate any food containing the fat-soluble factor, substituting instead extracts of vitamine A; xerophthalmia and night blindness were relieved immediately and the skin lesions underwent involution in approximately seven to eight weeks.

When proper therapy is instituted, the first evidence of healing of the skin is usually the reappearance of moisture in the folds of the large joints and about the genitalia; this occurs as early as the second week. There seems to be evidence that this represents a direct effect on the sweat glands proper, rather than one concerned with the replacement of desquamated keratinized epithelium by normal epithelium, a process that would require more time. Ocular lesions begin to heal in from one to two weeks in many cases and may be completely cured in about one month. The follicular skin lesions require, with some exceptions, from 2 to 3 months to undergo complete involution (Frazier and Hu), though delicate "atrophic scars" generally remain at the original sites, surrounded by a narrow zone of pigmentation. It seems, then, that much more time is necessary for the skin to become normal in vitamin A deficiency than in scurvy, the latter requiring about one week to 10 days for resorption of hemorrhage and about 2 to 4 weeks for disappearance of the milder keratotic accumulations. In those cases where several months elapse before the hyperkeratosis is replaced by normal tissue, there is

reason to suspect the additional factor of vitamin A deficiency. Finally, it remains to be noted that in evaluating the results of a therapeutic test in patients suffering from deprivation of the fat-soluble factor, there will be slower healing of all the manifestations whenever there is interference with the absorption of vitamin A or the conversion of carotene into it (diarrhea, liver disease, etc.).

SUMMARY

Following the presentation of two typical cases of vitamin C deficiency, there are presented clinicopathologic data indicating that the perifollicular petechial lesions, pathognomonic of scurvy, are distinguishable from the primary follicular papules seen in patients suffering from lack of the fat-soluble factor. The diagnostic importance of these eruptions and the criteria for their recognition are considered at length. The possibility of both deficiencies coexisting in the same patient is discussed on the basis of a critical evaluation of the literature on the subject, with particular regard to their modifying influence on the attributes of the skin lesions.

WATER BALANCE

WE all recognize the importance of a normal water balance in the body with the avoidance of dehydration on the one hand and of edema on the other. When the sick patient is unable to take sufficient water, salts, and food by mouth, he must be supplied with them in some other way and this treatment may be the chief aid in carrying him over a critical period in his illness.

The exact amount of water, salts and dextrose needed and the way the body uses them is not always appreciated. Water is usually of the first importance, and since all patients unable to take water by mouth are short on food, some dextrose is also needed. The indications for giving sodium chloride are not so simple.

The value of saline solutions for patients who have lost sodium chloride by bleeding, vomiting, diarrhea, sweating, etc., has been well established, but there is a tendency to use routine saline solutions for all parenteral therapy whether sodium chloride is needed or not. In the latter case, salt retention and edema is not uncommon. Malnutrition and sepsis may play an important part in this water retention, but the excessive use of sodium chloride is generally the precipitating factor.

Coller and Maddock* and their co-workers have recently done a useful service in gathering facts about the water requirements and in studying the water exchange of a group of sick surgical patients who were given the commonly used intravenous fluids. They have tried to find out both the amount and kind of such fluids which best supplied their patients' needs.

Some of the arithmetic of normal water exchange is well worth remembering. Let us first consider the amount of fluids. In health, the water content of the body is kept fairly constant by a nice balance between intake and output. Fluids drunk vary from about 800 to 2000 c.c., depending on the weather. The water content of food is often underestimated; on a routine diet the food furnishes about 90% of its weight in water from its own water content, plus the water formed by oxidation, namely about 1000-1500 c.c.

The amount of water lost in the urine is about 1500 c.c. and the amount needed for vaporization from the lungs and skin to control body temperature is about 2000 c.c. The amount lost in the feces is small, 150 c.c. or less. The vaporizing process is little effected by the amount of water available while the kidneys are greatly effected and must excrete waste products in the water which is left after other processes are cared for.

Dehydration occurs on many occasions with low intake of fluid such as the day of a surgical operation and just after it, in periods of nausea or food restriction, and with abnormal losses by sweating, loss of blood, diarrhea, vomiting, fever, etc. When a patient is taking nothing by mouth, nearly all of this 3500

c.c. of fluid must be supplied parenterally; if the patient takes some fluid by mouth this can be deducted from the 3500 c.c. total; if abnormal losses of fluid occur they should be added to it.

When the patient enters a hospital in a dehydrated condition, he must not only receive enough fluid for a normal water exchange, but an extra amount to make up for water previously lost. When water is given to such a patient most of the first day's intake goes to replace fluid previously lost, then water for vaporization is needed, and, last of all sufficient water becomes available for the urine.

Next, let us consider the kind of fluids. Coller and Maddock found that in a group of sick surgical patients receiving 5% dextrose in normal salt (or Ringers) solution, all retained water and gained weight, but when the fluids were given as before but the salt omitted, all promptly lost the water they had retained and the edema disappeared, even with a good water intake. In another group of sick surgical patients given equal amounts of 5% dextrose in distilled water, no water was retained.

It is obvious that warnings about the production of edema with salt solutions are well founded and should be remembered and the only reason gross water retention is not seen more often with the routine use of salt solutions is that they are usually given for only two or three days. When parenteral fluids are needed, the thoughtful physician will avoid mistakes by supplying only the amount and kinds of fluids and salts needed and skillful handling of this problem will often save the life of the very sick patient.

Franklin W. White, Boston, Mass.

PORPHYRINS AND PORPHYRINEMIA

THE porphyrin structure of four pyrrole rings occurs as an essential constituent of the hemins, chlorophylls, and at least some of the respiratory enzymes (cytochrome). While the free porphyrins occur in very minute amounts in living organisms, the biological importance of their derivatives makes it obvious that the study of porphyrin metabolism deserves close attention.

The porphyrins of importance in human metabolism are few in number. Chemically, they differ chiefly in the number of carboxyl groups in the side chains, but these small differences are associated with very marked changes in biological properties. Perhaps the most important porphyrin in man is protoporphyrin which is combined with iron to form the natural hemin of blood and tissues. The porphyrin which appears in the bile and urine of normal individuals is principally coproporphyrin. Hijmans van den Bergh has shown that if the liver is perfused with a solution containing protoporphyrin, coproporphyrin appears in the bile. Since protoporphyrin has a powerful photosensitizing effect, this power of the liver represents an important detoxifying mechanism. Besides copro-

*Frederick A. Coller, Vernon S. Dick and Walter G. Maddock: "Maintenance of Normal Water Exchange with Intravenous Fluids." *J. A. M. A.*, 107, pp. 1522-1526, Nov. 7, 1936.
Walter G. Maddock and Frederick A. Coller: "Water Balance in Surgery." *J. A. M. A.*, 108, pp. 1-6, Jan. 2, 1937.

porphyrin and protoporphyrin, mesoporphyrin and uroporphyrin occur in smaller quantities in living organisms or their excreta.

A complication in the study of porphyrin metabolism is the fact that each of the porphyrin types may exist, at least theoretically, in the form of a number of isomers. However, most natural hemins, chlorophylls, and bilirubin are derivatives of the 3d isomer type (III) and only one other isomer, the I type, occurs naturally. Since protoporphyrin is readily produced in the laboratory by removing iron from hemin which is obtained from erythrocytes, it would seem reasonable to believe that in the body protoporphyrin III would originate from a breakdown of the hemoglobin and, therefore, might, under certain conditions, be present in the blood in relatively large amounts. However, the amount of protoporphyrin as such which can be obtained from blood or red cells is extremely small; it is obvious that the healthy body does not allow the accumulation of this substance. The liver and the kidneys are the most important excretory organs in porphyrin metabolism, and it is significant that many cases of disturbance in porphyrin metabolism involve pathologic conditions in the liver or kidneys.

Recently, it has been found possible to develop methods for the quantitative estimation of the several kinds of porphyrins in urine, bile, and feces. So far, however, similar methods are lacking for use with blood and only qualitative or semi-quantitative estimates as to degrees of porphyrinemia are possible. Protoporphyrin is detectable in the erythrocytes of all humans. Watson has reported reticulocytes very rich in porphyrin. In cases of anemia with good regeneration, Seegal observed in the erythrocytes the characteristic red fluorescence of porphyrins in ultra-violet light. A variety of conditions such as fever, hemoglobin destruction *in vivo*, disturbances in metabolism of muscle cells, diseases of the liver, etc., may lead to an increased production or liberation of porphyrins which may be observed in the increased excretion of these substances. In these cases, in general, an increase in serum porphyrin is not detectable unless the normal excretory powers of the kidneys and liver are interfered with. If the secretion or outflow of bile is disturbed by blockage of the biliary passages, both bile bilirubin and bile porphyrin are increased in the blood stream, and the porphyrin in this case is not protoporphyrin but coproporphyrin. Coproporphyrin is generally found in detectable amounts in the serum of individuals with liver disease if there is a direct van den Bergh reaction in the serum. In patients with total biliary obstruction, the total porphyrin excretion is not altered, but the porphyrin practically vanishes from the feces and appears almost entirely in the urine. An increase in serum porphyrins can originate from the ingestion of foods containing large amounts of porphyrins (blood, muscle, etc.). An increase can also result from an abnormal intestinal fermentation and patients with liver disease in which this occurs may show a striking porphyrinuria.

Another source of increased porphyrin in the serum is from the action of toxic chemical substances such as lead, neo-salvarsan, and many lipid-soluble hypnotics and narcotics, including alcohol. These chemical substances not only result in an increased output of porphyrins, but may cause a formation of porphyrin

beyond the ability of the liver and kidneys to excrete them. For example, lead poisoning occasionally produces an increased porphyrin output in the urine along with a marked kidney degeneration; in these cases there is a striking increase of serum porphyrin of the coproporphyrin III type. It is significant in this connection that when lead compounds are added to liver pulp, hemin is decomposed to protoporphyrin instead of to bilirubin; presumably this same action takes place in the body with the addition of the conversion of the protoporphyrin to coproporphyrin by carboxylation in the liver.

In cases of congenital porphyria and the rare cases of very marked spontaneous porphyria, the harmful effects of the accumulation of porphyrins in the body are easily apparent. With smaller accumulations of porphyrins it is uncertain whether there is any harmful effect, but one must remember that porphyrins, when injected into humans, even in small amounts, can have a highly toxic effect.

It must be clear that we are only entering into our knowledge of this highly complex field, but the fundamental place of porphyrins in the vital processes in the body must give them great significance in the biochemistry and pathology of the human organism.

Ansel Keys and Joachim T. Brugsch,
Rochester, Minn.

DIET AND DIARRHEA

IT always has been, and still is, difficult to establish a rational attitude toward fueling that most efficient machine, the human body. The earliest forms of therapy had to do with the physical procedures of applying heat and massage and of changing from the customary to a different type of food. As these measures are readily available to everyone, the alert individual of not too many scruples as well as the less alert individual who blindly follows any and all notions, has utilized them to establish cures for what ails you.

In no field of medicine has there been such flagrant abuse, such absurdity in ideas, and such preying on gullible minds as in that of diet for gastro-intestinal disturbances. The less accessible a part is for careful study, the greater is the mysticism and the positiveness of advice in prescribing treatment. The weird suggestions that are made and the bizarre substances that are poured into the gastro-intestinal tract in the hope of benefiting persons who are troubled with constipation are really unremarkable in comparison to the limited, inadequate diets that are so characteristically ingested by patients who have diarrhea.

We all know of the suggestions that the sufferer partake only of cooked fruits and vegetables; of no "acid" foods, usually meaning citrus fruits and tomatoes; of no beef, pork or veal; of only puréed vegetables; of no milk or only of boiled milk, and so forth, not to mention the absurdities de luxe, such as the implication that it is a mortal sin to eat fried foods or to mix carbohydrates and proteins. Behind all these silly nonfacts is the germ of truth to which expression originally was given in the proverb, "One man's food is another man's poison"; in place of the proverb we now have the term "allergy."

We have heard so often the vivid description of the lettuce leaf or the dill pickle which erodes, digs, and sandpapers the ulcers of the intestinal tract! And we have been told how pepper and other substances sear and scorch the raw areas! Are these things so? Used as one expects an intelligent cook to use them, can these things actually do harm? The individual who is intolerant to certain foods must be kept in mind, but because some get hives from strawberries we don't condemn their use by all persons. Patients who have chronic ulcerative colitis, and especially the relatives of the patients, have all but swooned when the physician has permitted cakes and sausage for breakfast instead of the routine hot cereal, crisp toast and soft eggs!

Several fundamental facts must be considered in feeding persons who have diarrhea, irrespective of its type:

1. The food must be sufficient in amount. The well nourished individual who is normal in all ways except that he has diarrhea—diarrhea of the "habit" or "nervous" type—should cause no concern. But if the patient is depleted, thin or emaciated, whether the diarrhea is of a deficiency type or is the result of ulcerative colitis, his machine needs a most generous amount of fuel, more than if he were well.

2. The food must be adequate in quality. If the patient is intolerant of those foods which carry essential substances, especially the vitamins, minerals and proteins, then the physician must omit the natural foods and supplement with the now readily available concentrates. Probably he will overdo the feeding of vitamins but with less damage to the patient than formerly was done by giving not enough vitamins.

3. Food must be attractive and palatable. The subconscious fear that to eat much will increase the diarrhea is one great reason why these persons do not eat. Hence, a long period of being given puréed, mushy, messy appearing food more and more curbs the desire to eat. Why it is considered so heinous an offense to flavor with garlic, onion, spicy sauces, and so forth is hard to see. Not that a physician would advise chili sauce as a beverage or a plate of garlic as a meal for a patient who has diarrhea or any other condition; yet is it not absurd that temptingly seasoned foods are considered wrong?

This problem of diarrhea boils down merely to one of common sense. If a patient loses a fourth to a half of his food because of diarrhea, he must be given more, not less; if fried foods bother one patient, nevertheless they are not to be condemned for all, and so forth, and finally, for the physician to reason with himself and with the patient will do much to overcome absurdities in prescribing diets and in treating diarrhea. It remains a mystery how one can withdraw from a pigeon-hole a slip, printed weeks or months previously, and confidently offer that to the patient as "The Diet"; marvelous foresight would be required to know, weeks before a patient was seen, what to feed that patient. If it is justifiable to say that anything to do with the human body should be "tailor-made" certainly that thing is the prescription for his fuel. A rich and abundant variety of foods always is available nowadays but with better understanding of individual intolerances, it is possible to supplement with concen-

trates those substances which must be omitted from the diet.

Philip W. Brown, Rochester, Minn.

INDUSTRIAL PHYSICIANS ANNOUNCEMENT

OF special interest to every physician and surgeon of this country is the program of the American Association of Industrial Physicians and Surgeons 1938 meeting.

To broaden the interest in industrial medicine to the end of minimizing the morbidity and mortality of working people; reducing accidents and the number of deaths or cripples resulting therefrom; removing the hazards of occupational diseases, and keeping more people on the jobs in healthy condition—all these are naturally of vital interest to the physician or surgeon in general practice, for they mean more wage earners to assume and take care of more medical care for their respective families.

Acquaintance with industrial medical problems such as these is increasingly important to every physician and surgeon whether he be exclusively in private practice or identified, in whatever relation, with industrial practice. Thus, he will do well to mark on his calendar June 6, 7, 8, 9, 1938, for this meeting of the American Association of Industrial Physicians and Surgeons, which will be held concurrently with the Midwest Conference on Occupational diseases at the Palmer House in Chicago. The field of industrial medical practice is increasingly prolific of broader opportunities and closer cooperation with physicians and surgeons in every specialty and in every locality.

Scientific and technical exhibits will be a feature of this important and instructive convention, and any reference to exhibits should be addressed to A. G. Park, Convention Manager, 510 North Michigan Ave., Chicago.

PHYSICIAN HONORED

Dr. Anthony Bassler of New York City, has been decorated with the Legion of Honor of France for his work in medicine and gastroenterology.

NEWS NOTE

The medical staff of the Menninger Clinic will conduct its fourth annual Postgraduate Course on *Neuropsychiatry in General Practice*, April 25 to 30, inclusive, at the Menninger Clinic, Topeka, Kansas. The course this year will include a brief introduction to the fields of neurology and psychiatry and a specific application of this knowledge to the large group of cases of psychoneuroses, psychoses and psychogenic and neurological disorders which every physician meets in his daily practice. Suggestions made by those who took the course last year have been embodied in this year's program in order to make it applicable to the most common practical problems of the physician.

As in previous years, several guest speakers, prominent in the fields of neurology and psychiatry, will appear at the evening sessions of the course.

One of the greatest tendencies in the English language is that towards the shortening of words and phrases. Telephone becomes phone, automobile, auto, and "God be with you" is shortened to goodbye. And so, with this first number of the new volume, the last

two words of what was a rather unwieldy name are dropped, and purely for convenience sake, the title is shortened so as to read *The American Journal of Digestive Diseases*.

Abstracts

GERBELS, ERNST.

Radical Operation for Cancer of the Rectum with Preservation of the Sphincter Muscles. S. G. O., Vol. 65, No. 4, pp. 528-533, Oct., 1937.

On the basis of the work of Westhues on the spread of carcinoma of the rectum the author states that it is possible to excise a growth in the rectum and save the sphincter and much more often than it is being done today. Westhues found that carcinoma of the rectum very rarely spreads downward from the lower end of the growth and that lymphatic involvement upward rarely extends more than ten centimeters, or above the sacral promontorium. The growth does not extend through the pelvic fascia until very late.

The procedure which appeals most to the author may be of from one to four stages. The first stage is an exploration of the abdomen for distant metastases and the establishment of a colostomy in the left half of the transverse colon. The second stage is resection of the tumor following the Goetze method, which is given in some detail. The third step is the closure of any defect in the rectal wall by means of the skin flap made by the incision. At this time, which may be some months after the second stage, it may be possible to free some of the sigmoid colon and draw it down to make an anastomosis with the lower segment. The fourth stage is closure of the transverse colostomy.

In some instances continuity of the bowel may be made following the method of Makulicz or that of Kuetner, which is very similar.

In otherwise favorable cases the author prefers this method and preserves the sphincter and muscle when the tumor lies one and one-half or more inches above the sphincter.

The age of the patient, constitutional type, length of the sigmoid and other factors must be considered. The decision as to which procedure to follow should be made during operation.

Three figures and a bibliography accompany the article.

MAYO, CHARLES W. AND NETTROUS, W. S.

Carcinoma of the Jejunum. S. G. O., Vol. 65, No. 3, pp. 303-309, Sept., 1937.

The authors report an additional 31 cases of carcinoma of the jejunum in which the average age of the patients was 51 years. Twenty of the patients were men, while eleven were women.

The symptoms were cramps and epigastric discomfort with recurrent short episodes of intestinal obstruction. By carefully questioning the patient after operation a typical history may be obtained in almost every case. Anemia, loss of weight and strength, with the symptoms of obstruction, and the finding of occult blood in the stool are very suggestive findings.

While Roentgen findings are not specific they render the diagnosis presumptive by exclusion of the stomach and colon.

Frequently (in 5 of the cases) the diagnosis was obscured by the simultaneous existence of gall stones or duodenal ulcer (in 1 case).

The treatment of choice is resection and entero-anastomosis as was carried out in 15 of the cases reported.

Entero-anastomosis or Gastro-enterostomy may be performed as a palliative procedure. Metastases are a common accompaniment of these tumors and the prognosis is unfavorable.

Three figures, one table and a bibliography accompany the article.

N. M. Percy, Chicago.

BLAIDSELL, P. S.

Pathogenesis of Anal Fissure and Implications as to Treatment. S. G. O., Vol. 65, No. 5, pp. 672-677, Nov., 1937.

Because anal fissure is so poorly understood and is even more poorly treated, and because of the fact that patients relieved of the distress of this exceedingly painful lesion are so grateful, the author has undertaken to clarify the pathogenesis and outline a logical treatment of this condition.

Since the great majority of these fissures lie in the sagittal plane, either anteriorly, or more often, as is the case, posteriorly in the anal canal, it seemed logical to search those points for a peculiar factor either anatomical or pathological. An anatomical factor was found in the Y shaped divergence of certain of the sphincter fibers in their course to the coccyx posteriorly. This same factor to a lesser extent is present anteriorly. Crypts, haemorrhoids and hypertrophied papillae are rarely found at these points.

Severance of the superficial cephalad portion of the external sphincter muscle so as to conform with the Y is the logical treatment. The author uses a light vaseline pack to keep the wound open and has had excellent results in a large series of cases.

A small bibliography and 5 figures showing reconstructions of the anal sphincter mechanisms accompany the article.

N. M. Percy, Chicago.

MCCAUGHAN, J. M. AND COUGHLIN, W. T.

Posterior Gastrojejunostomy—An Unusual Error in Technique. S. G. O., Vol. 65, No. 6, pp. 824-828, Dec., 1937.

The authors review the text books and special monographs dealing with retro-colic gastrojejunostomy and find that not a single one adequately describes the technic of that procedure. They describe that technic and report a case illustrating an unusual error which was corrected.

The case reported is one in which the anastomosis was made on the right side of the middle colic artery and in which the afferent limb of the anastomosis was turned back on the efferent limb and partially obstructed. The procedures necessary to correct the mechanism in their case are described and illustrated. A bibliography accompanies the article.

N. M. Percy, Chicago.

ABSTRACTS

BRUNSWIG, S.

Resection of Head of Pancreas and Duodenum for Carcinoma. Pancreatoduodenectomy. S. G. O., Vol. 65, No. 5, pp. 681-684, Nov., 1937.

The author reports a case of carcinoma of the head of the pancreas for which resection of the duodenum and the head of the pancreas was successfully performed. The operation was performed in two stages. The first stage consisted of (1) Gastro-enterostomy, (2) Cholecystojejunostomy, and (3) Entero-enterostomy. The second stage consisted of excision of the pyloric end of the stomach, and the first and second portions of the duodenum and the head, with a portion of the body of the pancreas.

Post-operatively the patient survived a transurethral prostatic resection on the 20th day, and died on the 85th day following the second stage operation. Necropsy showed diffuse abdominal carcinomatosis, which was not present at the time of the operation.

This operation is reported because it seems feasible that it might be employed in cases of primary malignancy of either the head of the pancreas or the duodenum.

Five figures accompany the article.
N. M. Percy, Chicago.

GRANFIELD, G. P.

A Pharmacologic Study of the Mechanism of Gout. Ann. Int. Med., 11, 651-656, Oct., 1937.

As a result of animal experiments and clinical observations the author concludes that the excretion of uric acid may be modified by the autonomic nervous system. More specifically, the action of atropine on allantoic excretion is mediated through the parasympathetic whereas that on uric acid excretion is mediated by the true sympathetic. Separation of the two components of the autonomic nervous system was accomplished by pharmacological means using ergotamine and atropine.

The data presented suggest that the etiology of gout may well be sought in functional disturbances of the vegetative nervous system involving especially the innervation of the kidney.

Hanes M. Fowler, Fort Wayne.

FEIRO, GEORGE W.

Selenium, a New and Dangerous Hazard to Consumers. Consumer's Digest, 2:1-9, Sept., 1937.

Plants which have grown upon selenium-bearing soil may absorb selenium and certain kinds may absorb very large amounts of this extremely poisonous material and store it in an even more dangerous chemical combination than it was when present in the soil.

Almost any plant growing in such soil may become toxic to some extent.

Plants seem to be able to concentrate the selenium from the soil so that a plant grown on soil containing only one or two parts per million may contain thousands of parts per million. When a plant contains more than four parts per million it is considered dangerous to livestock.

Human beings are exposed to the effects of the poisonous material through the consumption of poisoned animal meat or grain grown upon the selenium-bearing soil. The author deplors the apparent lack of concern on the

part of state and federal departments of agriculture in investigating and reporting on the products of the regions where selenium poisoning of plants and animals may occur. In practically every report of federal or state departments of agriculture the economic loss due to death of live stock is stressed with little, if anything, being said concerning the consumer who eats the poisoned materials. In selenium-poisoned animals the poison is distributed throughout the body, accumulating in largest quantities in the liver. The part of the grain which shows the

Gastrophotor studies of the stomach reveal that Creamalin clings tenaciously to the peptic ulcer crater, covering it with a protective film. Thus a constant zone of neutrality is maintained in the ulcer area, protecting the exposed submucosa and muscularis from the erosive action of gastric juice, and permitting healing to progress unimpeded. These same studies disclose that other antacids, contrary to prevailing opinion, do not adhere to the ulcer.

Creamalin closely approaches the ideal antacid for peptic ulcer therapy. It fixes 12 times its volume of N/10 HCl in less than 30 minutes. It cannot lead to alkalosis, nor does it produce secondary rise in HCl secretion. In consequence, Creamalin promptly controls all subjective discomfort, and leads to remarkably rapid healing.

Reprints of published reports and the brochure "Present Day Concepts of Etiology and Therapy in Peptic Ulcer" sent to physicians on request.

greatest concentration is the gluten—a matter of some interest to invalids, since both gluten and liver are in the class of foods often recommended in special diets.

Selenium is a type of poison that produces irreparable harm to the system as demonstrated in laboratory animals and livestock. Liver changes in such animals are comparable to cirrhosis in humans. It has been pointed out that symptoms of selenium poisoning in animals show a marked resemblance to pellagra in man and the onset of the condition may be insidious so that the damage is done before the condition is recognized. A further question of interest is: could the average physician

recognize symptoms of selenium poisoning, particularly chronic poisoning?

The author stresses the fact that the state and federal departments of agriculture have apparently intentionally failed to properly inform the public regarding the existence and danger of use of selenium-poisoned grain and livestock produced in certain regions. In the United States, selenium is found in Arizona, Colorado, Kansas, Montana, Nebraska, New Mexico, Oklahoma, South Dakota, Utah and Wyoming.

A list of references bearing upon the subject is appended to the article.

NIXON, JAMES W.

"Primary Carcinoma of the Ileum." *Southern Med. Jour.*, 30:1049-1052, Nov., 1937.

Statistics quoted show that primary carcinoma of the small bowel is extremely rare and that the ileum is especially free from involvement. This is explained by the fact that the fecal contents of the small bowel, as contrasted to those of the large bowel, are liquid, alkaline and practically sterile and at the same time the character of the mucosal cells is such that the effect of the fecal matter becomes a matter of nutrition rather than of irritation.

The condition is seldom diagnosed correctly before operation. It is so rare its possibility is usually not considered, the signs and symptoms are quite similar to the more commonly seen conditions, there is generally no mass palpable, and the usual X-ray examinations do not give characteristic findings. Repeated attacks of vomiting and cramps, persistent blood in the stool, marked anemia and exhaustion with negative roentgenological findings should be suggestive of the disease.

The prognosis is extremely bad probably because of the rich lymphatic and blood supply. The rather low average age of the patients, around 44 years, may also be a factor.

The treatment indicated is resection of the tumor and restoration of the continuity of the bowel. While immediate aseptic anastomosis by the Rankin clamp is preferable the condition of the patient may require simple exteriorization and anastomosis at a later date.

A well described case is reported. Although the patient had metastatic mesenteric lymph nodes at the time of operation she was well fourteen months later. A good working bibliography is included.

For The Better Control of Arthritis

SALICI-VESS

(Salicylate-Iodide)

(Alkali-Effervescence)

Two established, safe, anti-arthritis, anti-rheumatic agents have been combined to give an improved synergistic effect—securing quick relief from pain and muscle spasm, rapid reduction of swelling and added comfort for the arthritic sufferer.

The presence of alkali-buffers is a further encouragement to successful therapy because it helps to protect against gastric upset and combat the mild acidotic condition so frequently associated with rheumatic affections.

Finally Effervescence helps pre-

vent stomach irritation, encourages rapid assimilation, insures greater ease of administration.

Salici-Vess is easy to take and as stated is unusually well tolerated.

The average dose is one to two tablets taken three times a day between meals, increased or diminished according to indications.

Supplied in convenient effervescent tablets—tubes of 30.

Investigate this new anti-arthritis by writing for clinical sample and descriptive literature.

EFFERVESCENT PRODUCTS, Inc.

PESSAGNO, D. J.

"Regional Ileitis with Involvement of the Cecum." *Southern Med. Jour.*, 30:1052-1055, Nov., 1937.

Regional ileitis has a number of confusing synonyms as regional enteritis, chronic non-specific granulomatous ileitis, chronic ulcerative ileocolitis, etc. Since the pathological process is a benign hyperplastic one and since the colon may also be involved the most descriptive and inclusive term would be "chronic non-specific granuloma of the intestinal tract."

No etiological agent has been satisfactorily demonstrated and the appendix can be excluded as a cause. The disease has been described as having four stages: the acute phase with localized peritonitis, the stage of active enteritis, the obstructive stage, and lastly, the stage where fistula formation occurs. Recovery has occurred spontaneously and after a simple en-

terostomy done even in the involved segment. On the other hand the disease has progressed after an apparently complete resection of the involved segment. No case has been reported wherein a fistula has perforated into the peritoneal cavity. In the acute stage the symptoms are suggestive of acute appendicitis which is the usual pre-operative diagnosis. The chronic cases should be more easily diagnosed since a mass can frequently be palpated in the right lower quadrant and X-ray examination may offer suggestive findings. A characteristic sign described by Kantor is "the string sign," a thin irregular line of barium seen in the terminal ileum stopping abruptly at the ileocecal valve and representing the lumen of the thickened contracted intestine.

There is no uniformity of treatment. In children and in cases where the mesentery is not involved an enterostomy may suffice. If the mesentery is thickened and indurated a side-tracking operation may bring about a cure. If it does not, resection, which is used primarily by some surgeons, can be done later.

A most interesting case is reported and an adequate bibliography is included.

J. Duffy Hancock, Louisville.

BEEMAN, J. A. AND HUNTER, W. C.

Fatal Nicotine Poisoning. A Report of Twenty-four Cases. Arch. Path., 24:4-481, Oct., 1937.

The authors report a series of twenty-four cases of death attributed directly to the ingestion of nicotine insecticides. Black Leaf 40, a commercial tobacco by-product containing 40 per cent nicotine sulphate, is widely used for the killing of aphids, a common parasite of the rose plant, and is obtainable without restriction in the local markets. It is probable that this insecticide had been used in most of the cases.

Eight cases came to autopsy. The essential findings were of two types: (1) hemorrhagic gastritis, with or without the odor of nicotine, similar in appearance to the gastritis produced by a mild caustic; (2) cases without gastritis, but showing acute failure of the right heart without an adequate anatomic basis for death. The lungs showed changes commensurate with moderate asphyxia; the kidneys showed a marked hyperemia out of proportion to the acute passive hyperemia elsewhere in the body; a brownish frothy material, similar to that of congestive pulmonary edema was noted about the face and nostrils of the body in nearly all cases.

An experimental study on cavyies with Black Leaf 40 and 40 per cent solution of nicotine alkaloid showed the presence of gastritis only in those

animals given the insecticide. All animals died in convulsions with fixation of the respiratory muscles. The renal hyperemia seen in man was not found in the animals. An attempt to isolate an irritant resin from the Black Leaf 40 as the cause of the gastritis was unsuccessful, but it was concluded that the local irritant action of it was not due to its nicotine content.

COVELL, W. P. AND WHEDON, M. S.

Effects of the Paralytic Shell-Fish Poison on Nerve Cells. Arch. Path., 24:4-411, Oct., 1937.

The above report is one of a series of studies on mussel poisoning which have been carried out at the George Williams Hooper Foundation, University of California, during the past several years by K. F. Meyer and his associates. Instances of fatal mussel poisoning have been known for years along the west coast of the United States—especially along the mid-coast line of California. The brilliant research of Meyer led to the recognition of a relationship between the appearance of poisoning in man from the eating of mussels and the presence at the same time of a marine dinoflagellate in the sea water upon which the mussels were feeding. The toxic factor acts, after being absorbed from the gastro-intestinal tract, as a depressor of respiration and inhibition of cardiac action; and also, according to Kellaway of Australia, as a "neurotoxin with both central and peripheral actions."

The above study revealed no alterations in the nerve cells of the central nervous system in acutely poisoned animals. In chronically poisoned animals, however, there were changes in the large nerve cells of the ventral horn of the spinal cord and the ganglionic cells of the medulla. The mitochondria were normal in appearance in the nerve cells but showed definite damage in the convoluted tubules of the kidney. It seemed probable that the changes in the nerve cells of the medulla and spinal cord were due to a direct central action of the poison. The slow elimination of the poison from the kidneys may be responsible for the alterations in the mitochondria of the tubule cells of the latter. It is possible also that further study will reveal early changes in the peripheral nervous system, in particular the end organs, to explain the parasthesias which appear early in clinical cases of mussel poisoning in man.

HURST, A. F. AND KNOTT, F. A.

Regional Colitis. Guy's Hospital Reports, 87:187-198, April, 1937.

Regional colitis is an uncommon condition, in which typical ulcerative

colitis is present in a localized area of the colon which does not include the lower part of the pelvic colon and rectum.

The symptoms are those of ulcerative colitis, but the sigmoidoscope shows a normal mucous membrane. The area of colon involved can be accurately localized with the X-rays after an opaque enema.

Two cases of regional colitis are reported, one in which the proximal half of the pelvic colon was involved and responded very well to medical management. In the other, the descending and iliac colon were involved and recovery followed removal of the affected area. Bacterial investigations led the authors to conclude that the latter case was a result of infection with *B. asiaticus*, the cultural and other characteristics of which are described.

Hanes M. Fowler, Fort Wayne.

COLBECK, J. C., HURST, ARTHUR F. AND LINTOTT, G. A. M.

Regional Ileitis (Crohn's Disease). Guy's Hospital Reports, 87:175-186, April, 1937.

Two cases of regional ileitis (Crohn's disease) are reported. In the first, recovery followed a short-circuiting operation without excision of the affected bowel. In the other case recovery followed resection of the involved area. Complete pathological and bacteriological reports of the specimen are presented. There was no evidence whatsoever from the bacteriological study to indicate that tuberculosis had any etiological relationship with the condition. Typical tubercle-like lesions were observed microscopically in the specimen.

There are two plates showing X-ray pictures of the condition, one plate showing the gross specimen, and two plates showing microphotographs of the tubercle-like lesions in the wall of the involved bowel.

The symptoms of the disease are discussed briefly and a plea is made for the observance of a reasonably restricted conception of Crohn's disease and of the grounds on which such a diagnosis can justifiably be made. The good prognosis resulting from suitable treatment is emphasized.

HILL, M. R., BARNES, R. W. AND COURVILLE, C. B.

Vesical Dysfunction Following Abdominoperineal Resection for Carcinoma of the Rectum. J. A. M. A., 109:1184, Oct. 9, 1937.

Resection for carcinoma is not infrequently complicated by bladder distention and retention of urine. As a result of continued obstructive or paralytic obstruction, cellulose or small diverticula may appear. The urinary

retention is variable in duration. It may be transitory or at times it is permanent. The extent and duration of vesical dysfunction depends on the amount of damage to the nervous elements. The fact that the parasympathetic elements are predominantly affected suggests that the pelvic nerves or parasympathetic elements in the hypogastric plexuses are the seat of the injury. The relation between the pelvic nerves and hypogastric plexuses and the lower part of the rectum penetrating the pelvic floor has been shown by anatomic dissections. If the upper part of the rectum or the lower part of the sigmoid flexure is involved, or if there is extensive affection of the regional lymph nodes with fixation of other organs or tissues, these nerve injuries are more apt to take place.

If there is more than 50 c.c. of retained urine an indwelling catheter should be used. Cystitis most often develops in patients who are not catheterized. It is treated by lavage of the bladder with potassium permanganate solution (1:6,000) and instillation of 15 c.c. of silver nitrate solution (1:1,000).

Francis D. Murphy, Milwaukee.

ABELL, I.

Acute Abdominal Catastrophies.
J. A. M. A., 109:1241, Oct. 16,
1937.

When the symptoms of acute ab-

dominal catastrophies are encountered the determination of whether or not the condition is operable is of utmost importance and often very difficult. Prolonged pain, nausea, vomiting and constipation generally indicate a surgical lesion, while diarrhea most often indicates a medical condition. A careful history and complete physical examination with blood and urine analysis should always be done in an effort to distinguish a medical from a surgical ailment.

Appendicitis is responsible for about 50 per cent of the emergency abdominal operations. Diagnosis is easy in typical early cases, however, if the patient is seen late, or if the appendix is in an atypical position there may be difficulty. In infancy and childhood recognition is hard. Pain, nausea, vomiting, fever, and leucocytosis should put one on guard. If gangrene or peritonitis has developed, the author considers that, after restoration of fluid, the necrotic, virulent tissue should be removed without undue trauma.

The high mortality rate in intestinal obstruction is due in a large measure to delay in operation. The site and character of obstruction is also important in prognosis. External obstructions, strangulated hernias, offer no diagnostic problem, but internal obstructions are hidden from view and obscure to palpation. Abdominal pain, nausea, vomiting, constipation with the

absence of fever and leucocytosis are suspicious signs, and audible or visible peristalsis with roentgenogram interpretation of fluid and gas levels are often diagnostic before the patient's condition becomes extremely grave. Fluids must be replaced and resistance may be built up by transfusion before operation. The type of operation must be suited to the lesion and the patient's condition. In infancy intussusception is the common cause of obstruction, in early adult life there may be hernia and peritoneal adhesions, and in later life carcinoma is the greatest causative factor.

If peptic ulcer is present perforation or hemorrhage demand emergency treatment. Acute perforations give rise to agonizing pain, nausea, vomiting, board-like abdominal rigidity, and sometimes shock. To delay operation is disastrous.

Diverticulitis in Meckel's diverticulum occasionally causes an acute abdominal catastrophe and there may be diverticula elsewhere. The symptoms closely mimic those of appendicitis.

Acute pancreatitis is infrequent and very similar in symptoms to perforated ulcer and cholecystitis, and therefore it is often not diagnosed. There are no pathognomic symptoms. Vomiting, pain, and collapse are encountered. Previous gall bladder disease, pain radiating from the right costal margin across the upper abdomen, tenderness over the

Controlling **INTESTINAL PUTREFACTION**

KAO-LACTOS B combines the valuable therapeutic properties of three widely-used adjuncts to the treatment of intestinal toxemia:

- Crookes Colloidal Kaolin:—aluminum silicate in an extremely fine state of colloidal subdivision to aid in removing bacterial toxins and to soothe irritated mucous membranes.
- Lactose:—to aid in the production of an aciduric flora.
- Vitamin B:—to assist in overcoming a deficiency which often induces anorexia and gastric and intestinal atony.

AVERAGE DOSE: 1 to 2 teaspoonfuls in water about one-half hour before meals.

Supplied in powder form in 4 oz. bottles

Literature to physicians on request.

KAO-LACTOS B

CROOKES LABORATORIES, INC. • New York, N. Y.

Therapeutic Preparations for the Medical Profession

In cases of hyperacidity and peptic ulcer the use of **LACTALUMINA**—the original colloid of aluminum hydroxide—is suggested to control excess acidity without interfering with normal digestive processes. Supplied in liquid form in 8 oz., 16 oz. and 80 oz. bottles.

pancreatic area, pain left of the upper midline, and a mass in the pancreatic area are helpful diagnostic signs when present. Prompt operation is necessary to relieve torsion, stop hemorrhage, prevent leakage, and afford drainage.

Ruptured ectopic pregnancy is not difficult to recognize. There is sudden pain, vomiting, faintness, anemia, collapse, rapid pulse, subnormal temperature. The author rehabilitates the patient with transfusion and operates immediately.

There is still difference of opinion about the treatment of acute cholecystitis. Atypical cases are confused with appendicitis, leaking peptic ulcer and pancreatitis. Gangrene and perforations are surgical emergencies, but delayed operations in inflammations are advised by some. The author, however, considers that operation should be done immediately because delay invites complications. Dextrose should be given, deviations in the blood chemistry corrected and the balance of body fluids restored before operation.

Francis D. Murphy, Milwaukee.

MARSHALL, S. F. AND KIEFER, E. D.

Partial Gastrectomy for Gastric or Duodenal Ulcer. J. A. M. A., 109:1341, Oct. 23, 1937.

The advisability of subtotal gastrectomy for gastric and duodenal ulcer is a controversial subject. It is impossible for one method to fit every patient and type of ulcer. 242 patients operated on for ulcer at the Lahey Clinic were studied. Preoperative determination of the type of ulcer is valuable so there should be a period of medical treatment and repeated X-ray examinations before operation. The selection of the type of surgical procedure is a complicated problem.

In partial gastrectomy the mortality rate is high. In the Lahey Clinic the policy in treating ulcer cases has been conservative, operation being done only when medical treatment was unsatisfactory or complications occurred. Subtotal resection more nearly meets the requirements for treatment—prevention of complications and recurrences—than any other procedure, but the hazards of the operation are great. The technic is described. The preoperative and postoperative management are of great importance. It is important to strive for post-operative acidity because of the occurrence of jejunal ulcer when the acid is not sufficiently reduced by partial resection. Unless acidity or hypo-acidity is produced, it is difficult to see any clinical advantage of this operation over gastro-enterostomy. In general the period of convalescence is extended. The final clinical results are quite satisfactory. In the series of 102 patients on whom gastric resection was done, 84 per cent are in good or excellent

condition, 9 per cent have symptoms caused by functional disorders, and 6.7 per cent have had postoperative ulcer.

Francis D. Murphy, Milwaukee.

BROWN, P. W. AND MARCLEY, D. M.

Prognosis of Diverticulitis and Diverticulosis of the Colon. J. A. M. A., 109:1328, Oct. 23, 1937.

The authors studied 596 patients with diverticulitis and diverticulosis of the colon at the Mayo Clinic and follow-up data were obtained in 86 per cent of the series. The symptoms observed were diarrhea, bleeding, inflammatory and obstructive symptoms, purulent rectal discharge, and fistula of the bladder. These may be lacking, moderate or severe. Ninety-nine patients were treated surgically. Fifty-seven recovered and 43 per cent either died after operation, or continued to have intestinal trouble. Medical treatment consists of rest, application of heat, dietary regulation and oral administration of olive oil. This regimen was used in 227 cases. Sixty-three per cent recovered, but in 37 per cent the results were only fair or poor. By regulation of diet and adhering to a definite regimen, however, many could live in comparative comfort and minimize the frequency and severity of the attacks. No evidence of a direct relation between carcinoma and diverticulitis was found.

Francis D. Murphy, Milwaukee.

GOLDEN, R.

Antral Gastritis and Spasm. J. A. M. A., 109:1497, Nov. 6, 1937.

Gastritis may be generalized throughout the entire stomach, but often it is limited or has its maximum effect in the antrum. This has led to the terms "antral gastritis," "pyloritis" or "pyloric gastritis." The symptoms may be the same as those of peptic ulcer including hemorrhage; or pain, vomiting and weight loss may suggest malignancy. The diagnosis depends on gastroscopic and X-ray examination.

This type of gastritis is associated with the "prepyloric syndrome." The involvement of the deeper layers of the stomach by inflammation probably accounts for the following physiological and anatomic changes: (1) prepyloric narrowing of varying degrees due to spasm, (2) abnormal, stiff, irregular peristalsis, (3) exaggeration, diminution or absence of mucosal folds, (4) hypertrophy of the pyloric muscles, (5) shallow mucosal erosions which are not demonstrable by X-ray or penetrating ulcer of the lesser curvature, (6) delay in emptying, sometimes resulting in a twenty-four hour gastric residue.

There is difficulty in the differentiation of antral gastritis from carcinoma. The most important differential point

is the demonstration of mucosal folds in the narrowed area which should be obliterated by infiltrating carcinoma. If atrophic gastritis has caused thinning of the mucous membrane, diagnosis is very difficult. A definite palpable mass is evidence in favor of malignant disease. The author has found repetition of examination after several days of lavage helpful, especially if definite stasis is present. If there is doubt, operation is advisable.

Francis D. Murphy, Milwaukee.

LAHEY, F. H.

The Management of Pulsion Esophageal Diverticulum: Based on an Operative Experience with Eighty-two Cases and a Follow-up Study of Fifty-three Cases. J. A. M. A., 109:1414, Oct. 30, 1937.

Pulsion diverticula far outnumber all other types of esophageal diverticula. A pharyngo-esophageal diverticulum is a protrusion of the mucosa through the muscular wall of the hypopharynx. The sac lies between the pretracheal and prevertebral fascia and its neck is surrounded by fibers of the inferior constrictor muscle and the cricopharyngeus muscle. The symptoms are accumulation of food in the sac and related obstruction to the passage of food into the esophagus. There are difficulty in swallowing, regurgitation, gurgling noises in the neck, choking, attacks of strangling or coughing, and loss of weight. Successful operative treatment involves complete removal of the sac and its neck, the protection of the patient from the development of cellulitis between the prevertebral and pretracheal fascia and extension of infection into the mediastinum. The author uses the two stage operation because it guards against leakage of contaminated esophageal contents into the mediastinum with consequent mediastinitis. In the series reported there were two failures, two who showed poor results and forty-nine who recovered.

Francis D. Murphy, Milwaukee.

WATSON, BERNARD A.

Clinical Significance of Glycosuria. Jour. Lancet, 58:1-4, Jan., 1938.

The incidence of glycosuria on routine examination is 0.5 to 2.0%. Sixteen to 20% of patients showing glycosuria are found to have disturbed glucose metabolism as judged by the glucose tolerance test. Regardless of the cause, glycosuria only occurs either in the presence of a lowered renal threshold for glucose or an elevated blood sugar, e.g., above renal threshold for glucose.

A simple fermentation test to differentiate glucose from other reducing substances is given. It is pointed out that excess of certain normal constitu-

ents in the urine may give a positive reducing test, as well as certain drugs that are listed.

Determining whether glycosuria is transient, post-prandial, or persistent, will aid in determining the severity of the underlying causes. Glucose tolerance tests done under carefully controlled conditions are an invaluable adjunct to the early diagnosis of a disturbed carbohydrate metabolism. If

fasting and 2½ hour blood sugars are the same, regardless how high the others may go, it is unlikely that diabetes exists. Figures for normal glucose tolerance tests and the more common variations are given. Early diagnosis of diabetes mellitus means early treatment with a better prognosis.

Hanes M. Fowler, Fort Wayne.

KEETON, ROBERT W.

Clinical Problems in Diabetes. Illinois Med. Jour., 73:31-38, Jan., 1938.

The author stresses the importance of educational training of diabetics with regard to the proper use of diet and insulin. Diets should be prescribed in the proper amounts just as drugs are prescribed in the proper dosage. Converting the diet prescription into an acceptable diet requires knowledge of foods and falls in the field of dietetics.

Several cases are cited illustrating the advantages of the use of protamine insulin.

Complications frequently seen in diabetics whose diets have been deficient in certain food elements are, a pellagra-like syndrome with uncontrollable diarrhea, and peripheral neuritis. These conditions respond to the adequate use of vitamins B₁ and B₂, respectively.

Diabetics with impaired peripheral circulation should have bed rest and treatment designed to facilitate the establishing of collateral circulation such as constantly controlled heat.

In cases of gangrene early adequate amputation is the treatment of choice. In cases where delay seems advisable, particular attention must be paid to care of the affected area. The surrounding temperature should be lower than body temperature to lessen autolytic digestion.

Hanes M. Fowler, Fort Wayne.

ABELL, IRVIN.

The Treatment of Peptic Ulcer. Ann. Int. Med., XI, 762, Nov., 1937.

The problem is recognized by the author as a medical one, primarily. Complications, sequelae and intractable chronicity constitute a triad, giving it a surgical aspect. When surgical interference is thought to have become necessary, a quiescent state of the ulcer makes the operation a safer one. The type of operation should be determined by the conditions and complications found at laparotomy. Massive resections have not been done on the basis of removal of the acid-bearing portion of the stomach. The selection of the case for operation, the author thinks, is the joint function of the physician and the surgeon. Perforations should be closed immediately. 80 per cent of duodenal perforations occur on the anterior wall and 90 per cent of acute perforations of stomach ulcers are found on the lesser curvature of the pre-pyloric portion of the stomach; perforation on the posterior wall is often sealed with adhesions.

Massive hemorrhage or a persistency of bleeding occur in about 25 per cent of all cases. Nothing short of complete

A
**VITAMIN
A & D**
Supplement

FOR USE THE YEAR 'ROUND

VITAMIN A AND D PREPARATIONS have long been associated with winter ailments—yet infants, children and pregnant women need a reliable source of these vitamins the year 'round. It is likewise true that patients may be averse to taking large quantities of cod liver oil—particularly during warm weather—or to spend a lot of money for vitamin preparations.

These objections have been overcome in Navitol—a product higher in potency than

halibut liver oil with viosterol, yet costing only half as much.

Navitol is a blend of specially selected, highly refined fish liver oils supplying, per gram, 55,000 units of natural Vitamin A and 10,000 units of natural Vitamin D (U. S. P. XI). Ten drops (or one 3-minim capsule) supply 9400 units of Vitamin A and 1700 units of Vitamin D (U. S. P. XI).

Supplied in 5-cc. and 50-cc. dropper bottles and in boxes of 25, 100, and 250 capsules.

NAVITOL MALT COMPOUND

An economical and inclusive dietary supplement, which presents in a palatable syrup, an abundance of Vitamins A, B, D, and G in natural form; also calcium, phosphorus, and liver extract in therapeutically beneficial quantities. Distributed in 1-pound and 2-pound wide-mouth jars.

For literature address Professional Service Dept., 745 Fifth Avenue, New York

E. R. SQUIBB & SONS, NEW YORK
MANUFACTURING CHEMISTS TO THE MEDICAL PROFESSION SINCE 1858.

NAVITOL SQUIBB NATURAL
VITAMIN OIL

eradication avails. Malignant degeneration of duodenal ulcer is not expected and hence chronicity scarcely constitutes a reason for surgical interference. Gastro-enterostomy is ranked as an infrequent procedure in dealing with duodenal ulcers because eradication of the ulcer is not deemed imperative; when eradication must be done the cautery method of Balfour is preferred with a posterior gastro-enterostomy. Malignant changes are common enough in ulcers of the stomach, hence removal or destruction of the ulcer is advocated.

Various types of operative procedures are discussed. The opinion is expressed that with proper selection of patients for operation, judgment in choice of procedures combined with proper supervision for at least a year after operation offer good prospects for relief.

Without qualifications the author concludes with the statement that "in the vast majority of patients presenting gastric symptoms, the latter are

due to causes extrinsic to the gastric tract."

Virgil E. Simpson, Louisville.

PORTIS, S. A. AND JAFFE, R. H.

A Study of Peptic Ulcer Based on Necropsy Records. J. A. M. A., 110:6, Jan. 1, 1938.

Although there is much literature on the surgical and clinical aspects of peptic ulcer, necropsy studies are few. The authors have studied the incidence of peptic ulcer in 9,171 consecutive necropsies performed at Cook County Hospital, Chicago, from 1929 to 1936.

There were 457 cases of peptic lesions, or a total of about 5 per cent. The incidence of ulcers was greater in white people than in negroes and more were found in white males than in white females. The ulcer was active in 339 of the 457 cases, and 118 instances it was the essential lesion. In almost twice as many it was incidental. The site of the ulcer was the duodenum most often when it was the essential lesion and gastric ulcers were more common in the incidental cases. In the male most ulcers occurred between the ages of 51 and 60 years and in the female two peaks were found—31 to 40 years and 61 to 70 years. When peptic ulcer was the essential lesion death was caused by hemorrhage in 18.3 per cent of the cases, perforation in 20 per cent of the cases, and stenosis in 7.5 per cent. Hemorrhage was more frequent in the stomach and perforation occurred more often in the duodenum.

The greatest incidence of peptic ulcer coincides with the age period when arteriosclerotic changes take place. In those cases where ulcer was an incidental lesion, it most frequently accompanied cardiovascular disease. It is concluded, too, that gastric ulcer tends to be acute while duodenal ulcer is more often chronic.

Francis D. Murphy, Milwaukee.

SPRUNT, T. P.

Cirrhosis of the Liver. J. A. M. A., 109:1945, Dec. 11, 1938.

The most valuable information for the diagnosis of hepatic disease is obtained by careful clinical history and physical examination. In some cases liver function tests are desirable; however, there is no single reliable test. One of the most important clinical signs is jaundice. When liver function is oppressed urobilin accumulates in the blood. Urobilinogenuria is an indication of depressed liver function. Jaundice may be of the retention type (bilirubin accumulates in the blood and given an indirect van den Bergh reaction) and the regurgitation type (bile escapes into the tissue spaces and blood sinusoids due to obstruction or necrosis and given a direct van den

IN CONVALESCENCE — Horlick's Proves Valuable

Patients convalescing from winter ailments find Horlick's not only strengthening, but pleasant in taste. This Original Malted Milk is especially convenient to prepare at any time.

1. Easy to digest — A bland diet food, enzyme processed — a unique vacuum method used. This Original Malted Milk is already partially predigested.
2. Highly nourishing — Full-cream milk combined with nutrients extracted from wheat and malted barley. A good to excellent source of vitamins A, B and G. Provides important minerals.
3. Tempting to the appetite — Patients with finicky appetites find Horlick's malt flavor appealing — important in providing nourishment.

Horlick's Malted Milk Tablets are convenient for frequent feeding, day or night. Children regard them as a confection — a happy solution to the problem of nourishment for the small patient.

For the Aristocracy of The

Your highly valued Journal is made to order for the aristocracy of thou.
of the Medical Profession of America . . . it has become a habit with m
and I would not care to miss a single issue.

The AMERICAN JOURNAL OF DIGESTIVE DISEASES.

Was NOT established as a *vade mecum*, a news magazine, a humorous monthly nor a fictional alleviation for the jaded nerves of busy doctors . . Most readers by this time have divined this point of policy, and have come to know that, month by month, this periodical gives a cross section of current and modern gastro-

enterological thought. It sees most of the manuscripts in this specialty: it prints all of them that are suitable . . . BETTER articles will be printed only when BETTER articles are written. The reader may confidently believe that at present the best work in gastro-enterology finds its way into these pages . . . Another way of saying that the management of this JOURNAL is seeking to perfect a really worth-while Archive in a most important field.

It is the firm intention of the Editorial Council that the pages of this Journal shall be kept FULL of important matter, and entirely EMPTY of all matter that is irrelevant . . .

Readers feel today that an important contribution to American Medicine is being, and will be, made through the agency of the American Journal of Digestive Diseases . . .

I am an admirer and reader of your excellent magazine.

You cannot improve on the editorial content—it is and should be, an outlet for scientific thought.

Material and format are excellent. I enjoy it very much because the articles are scientific.

It is certainly a well edited Journal and anyone who subscribes to it certainly gets his money's worth.

Quality brevity, educational value, scientific dignity, good typography and singleness of purpose are making friends in increasingly large numbers.

No Other Special Medical Journal Ever Made the Subscription Showing in 4 Years That Has Been Accorded to the American Journal of Digestive Diseases

With only the numerically small American Gastro-enterological Association as a formal backer, this Journal has independently attracted a record group of constant readers.

WHY?

The reasons are obvious —

- One of the strongest Editorial groups in American Medical Journalism, realizing the void that existed in gastro-enterological literature, determined to make a special Journal that would meet very specific needs.
- The needs were for a journal that would collect and attract under one head the important contributions in this field, thus enabling the reader to learn what he wished without the inconvenience of looking through an extensive literature.

- This has been done . . . today our Editor receives countless manuscripts from the investigators of the U.S.A. . . . today numerous readers volunteer the fact that they have never made better investments than in the Volumes of the American Journal of Digestive Diseases.

Spend \$6.00 per year or \$10.00 for two years NOW.

Join the increasing Group of doctors, whose enthusiasm has made and is making history in American Medical Journalism.

Young Stomachs— and Old

Would it not be a reasonable analogy to say that the digestive organs of a newborn infant and those of an adult afflicted with a digestive disorder are in a sense quite similar?

Both require foods that are bland and easily digested, for, of course, foods other than these may easily have irritating effects resulting in serious digestive disturbance.

Does it not therefore follow, and very logically, that Pet Milk, which by extensive use has proved to be extraordinarily suitable for the feeding of infants, even those prematurely born, should be equally well adapted for use in the dietary employed in the treatment of adult digestive disorders?

And would it not be sound therapy, when prescribing for the disordered digestive system, to specify Irradiated Pet Milk—a safe, readily digestible milk, containing an extra supply of vitamin D—and available at a lower price generally than ordinary milk.

We will gladly send literature and samples on request.

(Attach prescript on form or letterhead to coupon. Offer limited to physicians of Continental U. S.)

Bergh reaction). The former and milder form accompanies hemolytic anemia, congestive heart failure, malaria, and lobar pneumonia. The latter is associated with the major acute hepatic disorders. Ascites and a palpable spleen are usually obvious clinical conditions. When spontaneous diuresis occurs it is a favorable diagnostic sign. The disturbance in fluid balance may be related to reduction of the blood plasma proteins. Some students consider hypo-albuminemia an indication of hepatic insufficiency. The size of the

liver is important. It is enlarged in portal cirrhosis and decreased in toxic cirrhosis. Because of the great reserve power of the liver, function tests are important when the lesion is diffuse and widespread. The estimation of bile pigments in the urine, stool, duodenal contents and blood serum and the van den Bergh test for bilirubin in the blood stream are the most valuable aids. Other tests, excretory, carbohydrate tolerance, and protein metabolism, may be valuable in some situations.

Of the several kinds of cirrhosis, portal, toxic, pigmentary, and biliary, the portal type is the commonest. It is easily diagnosed by distended abdomen, firm edges of the liver, palpable spleen, dilated thoracic and abdominal veins, anorexia, nausea, coated tongue and offensive breath. There may be hematemesis and melena and secondary anemia. The urine is scanty and contains urobilinogen and mild jaundice is often present. The van den Bergh reaction and the excretory function tests are positive. In the earlier stage there is malaise, headache and depression and later delirium, drowsiness and coma are common. Depletion of liver glycogen reserve, pregnancy, toxic thyroid states, syphilis and its treatment and alcohol may all be etiological factors.

In treatment, the cooperation of the patient is important. Alcohol and irritating foods such as spices, condiments and pickles should be eliminated. The intake of protein should be cut to one gram per kilogram of body weight. Meat must be cut down and no fried foods are given. The diet must be high in carbohydrates. Cereals and starchy vegetables and dextrose in fruit juices are important. Sufficient rest and mild exercise are necessary. Other accessory methods of therapy such as iodides and calcium may be used and particular situations such as bleeding esophageal varices demand special attention.

WALTERS, W., MCGOWAN, J. M., BUTSCH, W. L. AND KNEPPER, P. A.

The Pathologic Physiology of the Common Bile Duct. J. A. M. A., 109:1591, Nov. 13, 1938.

In patients with lesions of the biliary tract, morphine, codeine and dilaudid produce a marked increase of pressure within the common bile duct because they produce a spasm in the sphincter at the lower end of the bile duct. The resulting biliary colic may be relieved by amyl nitrite, glyceryl trinitrate, and theophylline with ethylenediamine.

The authors suggest the use of morphine as a diagnostic measure. If an attack of pain which is relieved by glyceryl trinitrate results the evidence is in favor of some disturbance in the sphincteric mechanism at the lower end of the common bile duct either with or without stones. It is, however, valuable only as a temporary measure until the common duct has been explored.

DIET

When the impulse to defecate is lessened due to improper diet or lack of discipline, the fecal matter usually becomes dehydrated and impacted in the bowel. To simplify the problem of constipation, prescribe Petrolagar. It assists in the regulation of bowel movement. Petrolagar mixes intimately with the bulk of

the stool to induce a soft, easily passed mass. By reason of its pleasant taste and mild but thorough action, Petrolagar is agreeable to patients of all ages Five types of Petrolagar provide a choice of laxative medication suitable for the individual patient. Petrolagar Laboratories, Inc. • Chicago, Ill.

Petrolagar — Liquid petrolatum 65 cc. emulsified with 0.4 Gm. agar in a menstruum to make 100 cc.

Petrolagar

the rectum or lower sigmoid and spreads to the proximal segments, the descending and transverse colon and in severe cases eventually to the hepatic flexure, ascending colon, cecum and terminal ileum. In a certain percentage of cases, however, the lesion may begin in the hepatic flexure or ascending colon and involve the right side of the colon in a regional or segmental distribution, spreading to the more distal segments. Spontaneous recovery is rare in these cases.

The authors studied seventeen cases

of right-sided colitis and found them to be uniform in their outstanding characteristics. The two forms of ulcerative colitis are similar in general characteristics. Etiologically and pathologically they are the same. In right-sided colitis the course is less severe but it is progressive. The diarrhea is not as troublesome, involvement of the skin, buccal mucosa and joints is rare, and rectal complication less frequent. In right-sided colitis medical treatment is ineffective but permanent cure can

be obtained by surgical intervention without a disproportionate risk.

Undoubtedly, in the past, this type of colitis has often been overlooked, and with greater recognition its incidence will rise to greater than 10 per cent.

EDWARDS, MONTE.

"The Management of the Ano-Rectal Syndrome of Lymphogranuloma Inguinale." *Southern Med. Jour.*, 30:1194-1197, Dec., 1937.

While the clinical manifestations of lymphogranuloma inguinale are well recognized diagnosis should always be confirmed by the specific Frei test. In the ano-rectal region the onset of the disease may be fairly acute and febrile or relatively insidious but in either case there is congestion and edema of the rectal mucosa with a varying amount of purulent or sanguino-purulent discharge. Accompanying this irregularly shaped circumscribed elevated areas can be palpated. Constitutional symptoms may vary from practically nothing to pronounced weakness from toxemia and bleeding. Painful inflammatory swelling of the anus with or without fissure, may occur. Infiltration, suppuration, and necrosis proceed in a disorderly fashion and some tendency to cicatrization is always present. Cicatrization of course leads to stricture formation which is the nearest thing to arrest that can occur in the disease.

In the evaluation of medical measures it must be borne in mind that in spite of apparent intractability there is sometimes a tendency to temporary arrest. Bed rest is indicated at those times constitutional symptoms are present. The chief indication for surgical measures is the relief of the stricture. While complete obstruction rarely results absorptive phenomena accompanying the stricture will demand its treatment. Procedures used begin with periodic dilatation which may be very satisfactory, and include internal proctotomy, side-tracking the fecal current by a colostomy, and in some instances excision of the rectum. Colostomy should not be done without careful exploration of the left colon as the extent of the distase may necessitate placing the opening in the transverse colon. Since the disease is a progressive one the colostomy will in many instances be only palliative as in anorectal malignancy. Therefore, in selected cases, especially where the invasion is of the progressive hyperplastic type, or where improvement after colostomy is unsatisfactory a radical excision by either the perineal or abdomino-perineal route seems well justified.

J. Duffy Hancock, Louisville.

Pureed vegetables high in minerals and vitamins help avoid deficiency diseases from restricted diets

Rich in vitamins, minerals and other food elements by reason of scientifically bred-up vegetables, Gerber's strained vegetables are valuable aids in avoiding possibilities of anemia from restricted diets.

Vegetables, fortified soups and cereals, are all salt-poor, sugar-free and low in fiber. Pureed fruits are slightly sweetened. Ten years of authoritative research by the Gerber Products Company, with the continuous advice of leading medical authorities have served to raise these foods to their present high standard of nourishment and flavor.

Special strains of seeds have been developed to produce vegetables of greater nutritive content and improved flavor. Soil is analyzed and selected for the chemical needs of each kind of plant.

To capture the utmost flavor and food value crops are harvested precisely at their exact maturity. To conserve it they spend less than an hour en route from field to kitchen. Specially devised cooking processes exclude air to prevent damage, from oxidation, to avoid over-cooking, and otherwise conserve food values.

• Borden's Beta Lactose is now supplied in this new, more convenient container. No directions for use appear on, or in, the container.

Remember Beta Lactose in *Bacillus Acidophilus* therapy

● In accepting Borden's Beta Lactose, the Council on Pharmacy and Chemistry states that it "provides a favorable medium for the growth of the *B. Acidophilus*."

In comparison to ordinary milk sugar (alpha lactose), Beta Lactose is easier to use, because it is five times more soluble. Also, because it is more palatable, it's easier to take.

These two qualifications are worth remembering when prescribing lactose in the treatment of adult constipation associated with an improper or abnormal intestinal flora.

You are invited to make a personal examination of Beta Lactose. For a trial supply and further information, simply mail the coupon below.

BUNCH, GEO. H.

"Acute Phlegmonous and Non-Traumatic Perforative Lesions of the Colon." *Southern Surgical*, 6:449-457, Dec., 1937.

While the diagnosis and treatment of colitis and colonic ulcer are ordinarily medical acute phlegmonous inflammation and acute perforation of the colon are surgical emergencies. Such cases are quite rare and none of the four reported was correctly diagnosed before operation. One patient who had an incisional hernia at the scar of a previous appendectomy was thought to have an incomplete intestinal obstruction. Operation disclosed a diffuse peritonitis of undetermined cause which at autopsy was found to be due to perforation of a simple ulcer of the upper rectum at the peritoneal reflexion. A second case was diagnosed as one of spreading peritonitis probably from a ruptured viscus. At operation the general peritonitis was found to be complicated by a massive hemorrhage, a most unique occurrence. The descending colon near the splenic flexure was dark and discolored about a perforated ulcer and the bleeding was from a vein in the necrotic omentum near its attachment to the colon. The third patient was thought to have a diffuse peritonitis following a perforated appendix. Laparotomy showed a

massive phlegmon of the anti-mesenteric border of the ascending colon the appearance resembling a series of large confluent carbuncles in the gut wall, each with multiple erasers. Perforation of the bowel occurred during the operation and was followed by a fecal fistula and general improvement. However, on the 16th post-operative day the patient died of a right subphrenic abscess. The fourth patient was thought to have an acute appendicitis but at operation there was found an acute phlegmonous inflammation of sigmoid from acute diverticulitis. Recovery followed simple drainage but four and a half years later death followed a general peritonitis due to a perforated diverticulum in this area.

The resistance of the colon to the pathogenic bacteria it harbors is due to an immunity gradually acquired during life and when impaired inflammation and ulceration occur. Ulcers may result from mixed infections by unidentified organisms, may be due to specific organisms as occur in tuberculosis, syphilis, amebic dysentery and typhoid fever, may complicate systemic diseases or may follow thrombosis, embolism, or trophic changes in the gut wall.

Ulcers with marked tendencies to perforate have distinctive characteristics. In the beginning the lesion, though often multiple, is always acute,

clean cut and penetrating without undermining. Most cases are symptomless and unless the ulcer is in the lower rectum or about to perforate the pain is not severe and there is little tendency to bleed.

Phlegmonous inflammation in the colon may probably follow mechanical injury to the mucosa such as could occur from fish bones swallowed with foods. There are no pathognomonic symptoms; the ideal treatment indicated is resection if technically possible, drainage of the affected loop if not. In the sigmoid the phlegmonous inflammation is often due to diverticulitis, the involvement is usually segmental, perforation is rare, and while these are the cases best suited for resection they tend to resolution and spontaneous relief when treated by conservative surgical measures.

J. Duffy Hancock, Louisville.

carefully considered and surgical interference but rarely undertaken.

The usual treatment for hemorrhage consists of rest, morphine, ice-bag to abdomen, for five days or until the hemorrhage has stopped. Smithies preferred local heat to cold applications but neither measure is probably of any value beyond helping to keep the patient quiet and assure him that something is being done. While the starvation treatment is generally accepted the authors believed that food and alkalization as advocated by a few others was more rational. This treatment is based upon the view that frequent ingestion of small amounts of bland food causes less peristaltic action than hunger in an empty stomach and that frequent ingestion of alkalies and bland food would tend to neutralize the gastric acids, dilute the digestive juices and thus both prevent the digestion of the clot at the bleeding point as well as promote the healing of the ulcer.

The essentials of the plan of treatment used very successfully in a series of thirty-eight cases are as follows: (1) complete bed rest; (2) three to four ounces of cream and milk every hour from 7:00 a. m. to 9:00 p. m., started immediately unless contraindicated by vomiting or shock; (3) ten

one-fourth dram doses daily of an alkaline powder given in three or four ounces of water on the half hour between milk feedings; (4) instead of morphine which frequently excites nausea and vomiting and probably increases gastro-intestinal peristalsis, two grains of sodium-phenobarbital given intramuscularly every twelve hours, to be discontinued after two or three days and mild sedatives given orally; (5) tap water in small amounts as frequently as desired; (6) on the sixth or seventh day the addition of three small bland meals in addition to the milk and alkali mixture; (7) after ten to fourteen days six feedings daily of bland foods with the alkali mixture one hour after each feeding; (8) after ten days to a few weeks gastric analysis and X-ray examination; (9) transfusion when needed for shock; (10) when indicated five grains of desiccated ferrous sulphate three times daily for secondary anemia (which may result since blood regeneration may be delayed as a result of imperfect utilization of the dietary iron when the free hydrochloric acid is continuously neutralized) and (11) enemas rather than cathartics to eliminate putrified blood from the intestinal tract.

J. Duffy Hancock, Louisville.

MEDLAR, E. M. AND BLATHERWICK, N. R., WITH THE ASSISTANCE OF CONNOLLY, J. M., BRADSHAW, P. J. AND SAWYER, S. D.

The Pathogenesis of Dietary Nephritis in the Rat. Amer. Jour. Path., 13:6-881, Nov., 1937.

At the present time bacterial toxins and parenterally introduced proteins (nephrotoxins) are considered of greater etiological importance in diffuse degenerative changes in the kidney than are dietary factors. With this statement in the fore the authors detail their experimental studies on the production of degenerative nephritis in the rat when fed diets containing a large but varying percentage of protein. Rats with one kidney removed developed extensive nephritis more rapidly than intact rats. Likewise when desiccated thyroid was added to the diet nephritis developed more quickly. Thus a diet containing 0.4 per cent thyroid fed to 3 rats developed a fatal nephritis in 148 days, whereas 9 rats on a diet containing 0.1 per cent of thyroid lived an average of 539 days. Nephrectomized female rats on a diet containing 75 parts of dried beef liver also developed extensive renal damage in a relatively short time. This series of rats was studied in an attempt to recognize the progressive phases of

Decholin

REG. U.S. PAT. OFF.

THE COUNCIL ACCEPTED BILE ACID

- 1 Available in crystalline form, chemically pure...
- 2 Available in a white, compressed tablet without coating or coloring...
- 3 So low in toxicity that its sodium salt may be injected intravenously.

Decholin—c.p. dehydrocholic (triketocholanic) acid—is of established value in chronic cholecystitis, noncalculous cholangitis, hepatitis of toxic origin, biliary insufficiency. It increases

bile secretion by the liver cells 100% to 200%, and exerts a notable cholagogue influence. Contraindicated in mechanical obstruction of the bile passages.

Announcing **C-G ALKALIZER**

Effervescent **PALATABLE
EFFECTIVE
ECONOMICAL**

In response to a wide need for a palatable effervescent alkalizer at a moderate price, the Emerson Drug Company offers the profession, Emerson's C-G Alkalizer.

Emerson's C-G Alkalizer is an effective agent for supplying alkali in those conditions in which there may be reduced alkali salts in the blood, in addition to supplying calcium where systemic calcium deficiencies exist. Uric alkalinity, running four to six hours, may be induced by one dose, repeated in a half hour. Six teaspoonfuls will furnish as much calcium as the average daily diet. Emerson's C-G Alkalizer does not upset the normal acid of the stomach, is not laxative, but does stimulate gastric function as well as promoting elimination through intestines, kidneys and skin.

Available in four and eight ounce bottles at a maximum prescription price of 75c and \$1.25.

DUOCHOL

(PLESSNER)

in the treatment of

- ★ CHRONIC CHOLECYSTITIS
- ★ TOXIC HEPATITIS
- ★ STONE-FREE CHOLANGITIS

DUOCHOL exerts specific and dependable therapeutic influence upon the hepatobiliary mechanism. Its contained highly purified bile salts and sodium salicylate appreciably increase the rate of bile secretion and augment gallbladder evacuation. Drainage from both the larger bile ducts and the gallbladder is thus promoted, aiding in the removal of toxic accumulations and stagnant bile. Duochol produces prompt subjective relief and objective improvement in chronic cholecystitis, toxic hepatitis, and stone-free cholangitis.

Generous clinical samples of all Plessner bile products, together with literature, sent on request.

SPECIFIC MEDICATION in specific biliary conditions

Plessner bile salt preparations present specific medication for specific lesions of the hepatobiliary tract.

TAUROCOL (PLESSNER)

Taurocol is of unusual therapeutic value in mild chronic cholecystitis. Containing bile salts, stomachics, and laxatives, it enhances biliary drainage and stimulates intestinal peristalsis.

TAUROCOL Comp. (PLESSNER)

Contains pepsin and pancreatin in addition to the ingredients of Taurocol. Indicated when gastric or intestinal indigestion complicates chronic gallbladder disease, especially during pregnancy.

THE PAUL PLESSNER CO.
DETROIT, MICHIGAN

renal damage and led to the following observations.

The primary renal lesion appeared to be a damage to the filter bed of the glomerulus. Just how was not clear. The endothelium, epithelium and basement membrane were all involved. The primary damage was focal in nature with progressive focal lesions developing, thus presenting lesions of different ages in a single glomerulus. In time the large majority of the glomeruli become sclerosed. Focal areas of necrosis and hyperplasia of the epithelial cells and an increase of the basement membrane occur in the tubules distant from the intertubular blood vessels, a fact which led them to believe that these changes had resulted from the presence of substances passing through the altered glomerular filter bed. The early injury to the tubular epithelium led to necrosis of only a few individual cells but to a considerable hyperplasia of the epithelium. This state was followed later by necrosis and dissolution of the hyperplastic tissue. The authors deemed it possible to attribute these changes to a functional selectivity of the cells.

The alteration in the basement membrane of the tubules depended apparently upon the passage of substances through the epithelial covering. The process was progressive in nature in those areas where the tubular epithelium was involved, namely, in the glomerular capsules, the loops of Henle, and the distal convoluted tubule. The general distortion of the kidney architecture in advanced cases appeared related to the extent and degree of increase of basement membrane material. This seemed to be the cause of the interstitial fibrosis. Acute inflammation was nowhere seen. In the later stages lymphocytic infiltration was common in the interstitial tissue. Spontaneous infection did not appear to be significant in the series. The nephritis related to the given diets, was a progressive degenerative disease. The final picture simulated so-called arteriosclerotic nephritis in man with the arteries or arterioles remaining normal. The histologic picture in advanced stages in these kidneys was quite similar to comparable stages of nephritis in rats produced by "nephrotoxins."

The authors conclude that the etiological factors capable of causing progressive degenerative nephritis are probably multiple and may be quite diverse in character. It is also conceivable that the final pathological picture is the same regardless of the provocative agent. They suggest that progressive degenerative nephritis depends upon an irreparable damage to the filter bed of the glomerulus. It may be the toxic products of an infection, so-called nephrotoxins, abnormal metabolic products, or (at least experimentally) certain diets that initiate the process.

N. W. Jones, Portland.

**USEFUL IN MANY
INVALID AND
CONVALESCENT DIETS**

RIPE BANANAS are a natural, soft, bland food . . . with a delicate flavor . . . popular with most persons . . . nourishing . . . easily digested . . . mildly laxative . . . non-irritating . . . do not readily ferment in the intestines . . . create intestinal conditions unfavorable to the growth of putrefactive bacteria . . . yield alkaline mineral residues in the body.

Because of these attributes, together with their soft fibre, pectins, high content of sugars, satiety value, low content of protein and fat, their vitamins (good source of A-B-C-G) and essential min-

erals, ripe bananas are prescribed by an increasing number of physicians in many invalid diets, including: ulcerative colitis; peptic ulcer; cardiac; diabetes; liver disorders; nephritis; tuberculosis; as well as in various post-operative and convalescent diets.

In the field of corrective diets, physicians are finding that ripe bananas help combat both diarrhea and spastic constipation; also that in combination with milk they constitute a basis for planning a variety of effective, safe reducing diets for persons who are overweight.

THORNTON, JOHN W.

The Relation of Gall Bladder Disease to Certain Heart Conditions. Jour. Iowa State Med. Society, 27:573-577, Nov., 1937.

The author discusses the relationship of gall bladder disease and certain types of heart disease, such as angina pectoris and coronary disease, as regards etiology, symptoms, differential diagnosis, and treatment. Gall bladder disease may not be listed as one of the actual causes of heart disease but there is abundant evidence that it exerts a harmful effect on the heart already damaged. In the diagnosis it is important to decide whether symptoms are due to the heart alone, the gall bladder alone, or to both combined. Surgical treatment of a diseased gall bladder may improve the heart condition by removing a focus of infection or other damaging factors. Where gall bladder pathology exists, surgery in many cases need not be denied because of complicating heart symptoms, and these symptoms may even be added justification for surgery.

Simple Atrophy of the Liver—Its Relation to Increased Resistance. Arch. Path., 24:6738, Dec., 1937.

The author refers to recent experimental work of MacNider and of Smyth, Smyth and Carpenter, in which

certain morphologic changes from the normal is noted in the repair of renal and hepatic epithelium secondary to injury of these tissues. Hepatic epithelium as it regenerates is often found arranged in cords which do not run toward the central vein and are irregular in configuration. The cells are flattened and not polyhedral. The liver sinusoids are enlarged. There is no increase of connective tissue. This regenerated liver tissue is functionally effective, and has acquired distinct resistance to hepatotoxic agents, such as uranium nitrate, chloroform and carbon tetrachloride. This type of liver cell MacNider found also in 21 out of 92 senile dogs, and the livers of these dogs showed an acquired resistance to the action of chloroform—which control dogs did not possess.

The author calls attention to the similarity of these regenerated liver cells to those of simple, or brown, atrophy of the liver in man and suggests a relationship between simple atrophy and the body's resistance to toxic agents. With this thought in mind the author studied 387 livers from routine autopsies and found eleven which gave the morphologic picture described by MacNider. He postulates that these altered cells in human livers, similar to the altered cells in those of the dogs described which were found not to have lost their physiologic function and had become more resistant to toxic agents, may mean that persons with this type of liver may also be more resistant to these poisons, in which case atrophy assumes a new role in the phenomena of resistance and immunity.

BRIDGES, M. A.

A Pre and Postoperative Nutritional Regimen. A Proposed Fire Point Schema. New York State J. Med., 37:2009, Dec. 1, 1937.

The author urges a definite routine in preparing patients for surgery. For five days before the operation, the diet should be low in fats and high in carbohydrates to minimize the danger of acidosis. As much as one-half pound of hard candy may be given daily. Leafy vegetables with high roughage content should be avoided because of the marked incidence of spastic colon. One heaping teaspoonful (45 grams) of common table salt, administered in capsules, is recommended daily to improve weight. Sedatives, particularly the barbiturates, are helpful; catharsis immediately before the operation is condemned.

Postoperatively, fluids should be restricted for 48 hours to prevent nausea and possible overloading of the vascular system. The diet for the first five days should be semi-solid, and consist of small frequent meals. No benefit seems to be derived from insistence on diets with an alkaline ash residue.

NEW DISTINCTIVE UNIQUE DIET CHARTS!

Thirty-three specific diets, developed by some of New York's leading dietitians and minutely checked by practicing physicians.

Each diet is imprinted on a handy long-wearing celluloid card which can be permanently carried in purse or pocket without ever becoming soiled or worn.

Each diet enclosed in an individual personalized envelope bearing your name, address, telephone number and patient's name, date of issue and memorandum.

A real service to your patients—an entirely ethical opportunity for the physician to impress his name and service on patients and their friends.

Send for samples—gratis, of course!!

NEW HOPE FOR Age-Old Problems

Massive Doses of Vitamin D for Arthritis and Psoriasis*

Physicians throughout the nation increasingly report eminently satisfactory results with APOLARTHON therapy as an adjunct to other appropriate measures for arthritis. APOLARTHON is a NATURAL vitamin D preparation of extremely high potency and also contains natural vitamin A. The cost of APOLARTHON per VITAMIN unit is less than any other preparation available.

EACH CAPSULE CONTAINS
25,000 U.S.P. UNITS NATURAL
VITAMIN D

30,000 U.S.P. UNITS NATURAL
VITAMIN A

APOLARTHON

Available on Prescription
in Boxes of 60 Capsules, 55

The suggested dose for arthritic cases is from two to not more than six capsules a day. Systemic improvement is frequently noted within a few weeks and general symptomatic relief, pain greatly diminished if not entirely absent, lessening of swelling, and increased mobility of the joints within a variable period of time.

PROPERTIES OF KARO

Uniform composition
Well tolerated
Readily digested
Non-fermentable
Chemically dependable
Bacteriologically safe
*Non-allergic
Economical

*Free from protein likely to produce allergic manifestations.

COMPOSITION OF KARO

(Dry Basis)

Dextrin	50%
Maltose	23.2%
Dextrose	16%
Sucrose	6%
Invert sugar	1%
Minerals	0.8%

KARO EQUIVALENTS

1 oz. vol.	40 grams 120 cal.
1 oz. wt.	28 grams 90 cal.
1 teaspoon	15 cal.
1 tablespoon . . .	60 cal.

Artificial feeding consists of cow's milk modified to the degree of adequacy of breast milk. Most infants tolerate simple milk mixtures. But those with irritable gastro-intestinal tracts, limited digestive capacities or allergic sensitivities, require formulas adapted to their low tolerance.

Many processed milks are available for each type of infant feeding. But all forms of milk can be safely modified with Karo. It is adapted to virtually every formula devised for every difficult feeding problem.

ANO-RECTAL

General Practitioners and Medical Students will find sound advice in this new text. Based upon a wide clinical and teaching experience in proctology, this book can be relied upon to assist successfully in treating the type of cases that come under one's care in private or clinic cases.

In easily-read and crisp language the essentials for the accurate recognition and management of ano-rectal diseases are given. Strips of excess verbiage, in 16 chapters, are discussed authoritatively anatomy, physiology, symptomatology, methods of special examination, anesthesia and the majority of the functional and organic affections of anus and rectum which will be met in day-by-day practice. Differential diagnosis, pathology, and therapy—medical and surgical—are featured. The entire subject is emphasized and made clear by 174 black and white illustrations and six color plates. The technique of diagnosis and of therapeutic measures requires no elaborate array of costly instruments, nor does it require complicated and expensive electrical or other apparatus.

NORTHWEST MEDICINE—"This volume presents a valuable contribution not only to the proctologist but also to the general practitioner, comprising a synopsis of the more important phases of rectal diseases. The usual classification of ano-rectal diseases has been simplified. There are sixteen chapters with specific and general consideration to proctology."

By

LOUIS J. HIRSCHMAN, M.D.,
F.A.C.S., Professor of Proctology,
Wayne University, Detroit.

228 pages. 174 illustrations,
6 color plates. Price, \$3.50.

DISEASES

CONTENTS: Anatomy. Symptoms Which Should Call Attention to the Rectum. Examination of the Patient. Anesthesia. Limitations of Local Anesthesia and Office Treatment and Indications for Other Measures. Constipation and Obstipation. Fecal Impaction. Pruritus Ani. Anal Fissure and Ulcer. Abscess of the Ano-Rectal Region. Anal Fistula—Anal Sinus. Hemorrhoids. Ano-Rectal Polyposis—Anal Papillitis—Cryptitis. Proctitis and Sigmoiditis. Removal of Foreign Bodies, Benign Growths, and Rectal Stricture Prolapse of the Anus and Rectum.

WHAT REVIEWERS SAY:

CLINICAL MEDICINE & SURGERY—"If every general practitioner had this handy volume on his shelves, and consulted it frequently, as it deserves, rectal diseases would be better diagnosed and better treated; rectal carcinomas found early. The work is practical throughout, emphasizing simple, easily available methods of treatment."

MINNESOTA MEDICINE—"This volume is to be highly recommended to the general practitioner because the author gives a detailed, step-by-step outline of treatment accompanied by clear illustrations, and for the fact that practically all treatments given in the book can be accomplished in the office."

THE MEDICAL WORLD—"An ideal book that covers the subject adequately in small scope and at low cost."

Order Today—Pay in 30 Days

Under the Mosby Plan you can get Hirschman's book at once. Simply use the coupon at the right to order your copy. Read it. Use it for 30 days. Then send us your check for only \$3.50.

THE C. V. MOSBY COMPANY,
3525 Pine Blvd., St. Louis, Mo.

Gentlemen: Send me at once a copy of the new Hirschman "Synopsis of Ano-Rectal Diseases," priced at \$3.50. Charge my account.

Dr. Address.

BASIC OPERATIONS IN COMMERCIAL CANNING PROCEDURES

I. CLEANSING OPERATIONS

● As reference to a recent text on canning will disclose (1) the details of commercial canning procedures will vary from product to product. There are, however, certain basic operations which are included in practically all canning procedures. In the belief that they may prove of interest, it is our intention to describe in broad detail the nature and purposes of these essential operations.

One of the first and most important steps in commercial canning is the thorough cleansing of the raw food material received at the cannery. The purpose of such an operation is, of course, immediately evident, namely, to remove soil, dirt or other inedible substances which may be present. However, cleaning also serves to reduce substantially the load of spoilage bacteria with which Nature usually endows raw foods.

Commercially, cleansing is effected in a variety of ways. In general, however, water washers specifically designed for the various types of products are used. In these machines, the raw food material is subjected to high-pressure sprays or strong flowing streams of potable water while passing along a moving belt or while being tumbled by agitating or revolving screens. Sometimes a "flotation" type of washer is also used to remove chaff or similar material. With cer-

tain products, water washing is preceded by a "dry" cleaning treatment in which adhering soil and dirt is mechanically removed from the food by revolving or agitating screens, or by strong air-blasts.

Also, in certain canning procedures, operations whose basic functions are not primarily to clean the raw material may also exert a cleansing effect. Thus, the "blanch" or scalding treatment accorded many products serves to clean the food, as does the water spray sometimes applied to foods after the blanch.

Modern canners know the necessity of thorough cleansing of the raw materials they use. They appreciate that thorough cleansing and removal of extraneous material decreases the load of spoilage organisms which must be destroyed by the heat processes to which all canned foods are subjected. They also appreciate the necessity of maintaining strict plant and equipment sanitation to destroy spoilage bacteria which may be carried in by raw foods.

Because of the efficient cleansing of raw materials and close attention to the other important operations in the commercial canning procedures, modern canned foods must be ranked among the most wholesome foods coming to the American table. (2)

Research, Constant Research

continues to improve the quality of Mead's Brewers Yeast in the following respects, without increased cost to the patient:

1. Vitamin B potency raised to not less than 25 International units per gram. Also contains 42 Sherman vitamin 6 units per gram.
2. Bottles now packed in light-proof cartons, for better protection.
3. Improved bacteriologic control in harvesting and packing.
4. And NOW, since August 1, 1936, all bottles are packed in vacuum. This practically eliminates oxidation. Mead's Yeast stays fresh longer, as you can tell by its improved odor and flavor!

New Bucketless Lead Weighted Gastro-duodenal Tube with a Review of the American Contribution to the Development of These Tubes

By

MOSES EINHORN, M.D.
NEW YORK, NEW YORK

BEFORE describing my tube, I should like to give a general summary of the various types of tubes and buckets used for duodenal intubation, commencing with the early pioneering days to the present time, so that we may observe the gradual development of these instruments, and emphasize the special features which each author claimed for his tube.

The earliest pioneer work of successfully intubating the duodenum was accomplished in 1895, by Hemmester (1) who was the first to describe a device (Fig. 1, A), consisting of a tube connected with an inflatable rubber balloon the shape of the stomach, grooved on its upper surface for the passage of another tube into the duodenum through the pylorus.

Hemmester's work was soon followed by that of Kuhn (2) who in 1898, devised an instrument (Fig. 1, B), consisting of a "very flexible thin steel spiral tube, which was pushed through a thin stomach tube." The spiral served to prevent too much bending and kinking and doubling upon itself under pressure.

There was no further development along this field until about eleven years thereafter, when Dr. Max Einhorn started to experiment with his bucket. To him should be given the major credit for the first attempt to scientifically study the physiology of the duodenum, the pancreas and the gall-tract by means of the duodenal tube.

Max Einhorn experimented a number of years on various tubes and buckets, and finally in 1909, developed his duodenal pump (3), which consisted of a gold-plated perforated metal capsule (Fig. 1, C), tied at the end of a thin rubber tube. The terminal capsule is 7/8 inches in length, 23 French in diameter, and 59 grains in weight, and can be unscrewed for cleansing purposes. The main purpose of his duodenal tube is to allow the stomach to do the work of pushing the tube through the pylorus.

A few months later, Gross (4) described another tube (Fig. 1, D), somewhat similar to Einhorn's except that it was larger in size, and had a multiperforated silver-plated leaden ball at its distal end, 5 8 inches in length and 160 grains in weight, covered by the tube on all sides. Gross facilitated the passage of the tube through the pylorus, first by gravity of the leaden ball, and second by placing the patient in various positions.

Jutte (5) in 1912, devised a small calibered duodenal tube (Fig. 1, E), which has a lead sinker at its distal end, 4 8 inches in length, 12 French in diameter, and 21 grains in weight, with numerous small openings in the soft rubber tube above it. A wire obturator which acts as a stilette assists in the passage of the tube.

Palefski (6) in 1914, described his bucket (Fig. 1, F), which consists of a globular gold-plated lead tip,

6/8 inches in length, 34 French in diameter, and 140 grains in weight, 1/2 of which is solid, serving as a weight, and the other half hollow and perforated, terminating with a neck to which the tube is attached by means of silk thread.

He stressed the importance of weight, and claimed also, that a perforated ball acts as a sieve allowing the aspiration of the liquid only, leaving behind the particles of food, thus preventing clogging of the tube.

Rehfuss (7) in 1914, introduced a tube (Fig. 1, G), with a slotted instead of a perforated tip. The tip, which is olive-shape, is one inch in length, 29 French in diameter, and 90-100 grains in weight, with four elongated slots on either side, so cut that the diameter is as great as the calibre of the rubber tubing.

Rehfuss claims that in this manner we are assured a more perfect aspiration of the rubber tubing. The weight is sufficient to assure rapid swallowing, at the same time assisting by gravity its passage through the pylorus and into the duodenum.

Kanavel (8) in 1916, described his new tube (Fig. 1, H). The bucket is of the same shape as the Rehfuss, except that the lumen of the exit is larger. It is attached to a tube which is 30 inches in length, and 10 French in diameter. Through this tube a carrier of piano wire is introduced. After the insertion of the tube, the wire is withdrawn and the proximal end of the tube is attached to another tube larger in size, by a screw lock.

Kanavel claims that the piano wire carrier assists in the introduction of the tube, particularly in cases of vomiting; also, that the larger exit of the bucket permits the stomach content to be aspirated with greater freedom.

Buekstein (9) in 1919, modified the duodenal tube in a few details. He endeavored to get rid of the metallic end piece, since he thought it possible that a metallic weight of that sort might, if left in contact with the soft living membrane of the duodenum or jejunum over a long period of time during a course of duodenal feeding, produce an erosion with possible hemorrhage or ulceration. He introduced a modification consisting of a light weight tip (Fig. 1, I), 5 8 inches in length, and 23 French in diameter, which could be fastened to the duodenal tube by catgut. After a few days, the catgut stitch would be absorbed and the tip would become detached from the tube and pass out through the intestines to be recovered in the stool.

Lyön (10) in 1920, described a new tip (Fig. 1, J), elongated pear-shape, 9 8 inches in length, 27 French in diameter and 70-90 grains in weight, with four slotted openings on the sides, and a round perforation at its end. The tip is ground down to a tapering proximal end of the same calibre as that of the rubber

Fig. 1. New bucketless lead weighted gastro-duodenal tube with a review of the American contribution to the development of these tubes.

tube. Its shank is elongated and serrated, thereby doing away with the necessity of tying in the tip with surgeons' silk.

Lyon also emphasized the desirability of weight, and called attention to the difficulty which is encountered when the tube is withdrawn from the duodenal zone into the stomach, and more especially when it passes the pylorus on its upward journey, on account of the shoulder or collar on the proximal side of the olive and ball type tips. By having the neck tapered and narrow, this difficulty is eliminated.

Levin (11) in 1921, advocated the use of a tipless gastro-duodenal catheter (Fig. 1, K), which he preferred to introduce through the nose. It has a velvet edge at its terminal end exactly like a urethral catheter, 14 or 16 French in diameter, and side openings which are oval in shape.

Levin claims that by introducing the tube through the nasal route there is no tickling of the soft palate, the patient does not experience any discomfort or choking sensation, and it is easier to withdraw the tube, as there is no metal bucket at the end.

Hollander (12) in 1923, described his narrow tip

(Fig. 1, L), which is 9/8 inches in length, 10 French in diameter and about 100 grains in weight. There are four elongated fenestrae occupying about 1/3 of the length of the tip, situated at its upper portion. The lower part is solid lead filled shell, weighing 70 grains.

Hollander emphasizes the importance of weight, the lower part heavier than the upper part, and claims that a narrow tip can pass into the duodenum more readily than a wider one.

In 1926, I described my spiral bucket (13) (Fig. 1, M), which is 9/8 inches in length, 27 French in diameter, and 170 grains in weight. It is of capsule shape with an obtuse point, and has three divisions: (a) the top, made of nickel, through which a large opening is bored, which serves as an outlet for the drainage chamber to the tube, which is attached to the neck of the capsule (b) the spiral made of round metal wire, which connects the top to the body, and by its circular arrangement offers a large drainage area (c) the bottom, made of solid lead, and connected with the top by the spiral.

I also stressed the importance of weight, particu-

EINHORN—NEW BUCKETLESS LEAD WEIGHTED GASTRO-DUODENAL

Fig. 2. New bucketless lead weighted gastro-duodenal tube.

larly its proper arrangement, the distal end being three times heavier than the upper part, which aids it to travel along the small curvature and keeps it in proper place in its progress toward the pyloric opening.

In 1927, I described my analytic bucket (14) (Fig. 1, N), which is based on the same principle as the spiral bucket, but the lower part is constructed so that a space is left between the central column and the outer shell. It is in this space that the different paper strips prepared with Toepfer's solution, phenolphthalein, blue litmus and benzidine are inserted. There are four openings or fenestrae in the outer shell, so that fluids may take effect on the last strips. The bottom of the central column is so threaded that the bottom of the bucket may be screwed to it. The analysis of the gastric content is then made according to the change in the color of the paper strips.

Wilkins (15) in 1928 described his tipless mercury weighted stomach tube (Fig. 1, O). The tube is made of soft flexible rubber throughout, and measures 46 inches in length. It has a mercury compartment, $4\frac{1}{2}$ inches in length and $\frac{3}{16}$ inches in diameter at its lower end, as a result of which the tube at its end is very heavy. The openings in the tube are situated above the mercury compartment.

Wilkins emphasizes the importance of weight, and the fact that there is no metal about the tube which can injure the membrane of the stomach or duodenum, or become detached as the metal tips of tubes in common use can do.

Twiss (16) in March, 1933, described his new tube (Fig. 1, P), which consists of a small sized bucket with concave slots. A calibrated tube is attached to the proximal end of the bucket, and at its distal end is a swivel which is connected to a small solid terminal ball by rubber tubing of smaller size.

Twiss claims that the concavity of the slots will prevent adherence to the surrounding viscera and allow a free flow of fluid, and that the use of a swivel joint, prevents as far as possible, looping of the tube in the stomach; also, that this particular arrangement allows the concentrated weight of the tip to act as a leader in drawing the bucket through the pylorus into the duodenum, and also as an anchor in retaining it there.

Wangensteen (17) in 1933, stated that following abdominal operations, a paresis of the intestines of varying degree is the rule, and usually results in intestinal distention. He found from observation that a simple duodenal tube placed in the stomach does not keep the viscera continuously empty and so he developed a type of tube which he claims to give good results.

The tube (Fig. 1, Q) is 50 inches in length, weighted at its tip, and is processed for four inches at its terminal end to appear opaque for fluoroscopic examinations. There are nine openings which extend upward ten inches from the end of the tube.

Wangensteen believes that while the tube is in the duodenum, drainage is accomplished for the duodenum and the stomach at the same time. This is true if all the openings are below the fluid level, but in the event that one of the upper openings is above the fluid level, then syphonage will stop, and the rest of the fluid will be retained.

Ryle (18) described a tube which he weighted at the end with an oval shape lead piece covered with rubber on all sides.

From the description of the various tubes and tips given above, and from the advantages emphasized by each of their authors, we can summarize the salient points as follows:

1. The weight of the tip is an important feature in its construction.
2. The distribution of the weight, with the lower part three times heavier than the upper part is essential.
3. To eliminate injurious effects of the metal tip it is necessary that it be silver or gold-plated or covered with a layer of rubber.
4. The top of the bucket should be tapered and narrow and about the same size as the tube in order to remove the difficulty encountered at the glottis upon removing the tube.
5. It is desirable to have the openings in the tube, instead of the bucket, as the rubber margins prevent the cutting of the mucous membrane upon suction.
6. The openings should be slotted and smaller than the lumen of the tube, to prevent clogging by particles of food.
7. Tying of the neck of the bucket should be eliminated, as the rough edge of the knot may irritate the mucous membrane.
8. The tube should be so constructed that its openings or fenestrae do not lie flat on the visceral wall, but are raised to permit a continuous flow or drainage.
9. The bucket and tube should be constructed in one unit, to eliminate the possibility of its becoming detached, which is usually feared by the patient.
10. An increased number of openings extending along the lower end of the tube does not tend to increase the flow, but on the contrary, if one of the

upper openings is above the level of the fluid, syphonage will cease, and the rest of the fluid will be retained.

11. Catheter type tubes are satisfactory for introduction through the nasal route, but in gastric and duodenal intubation a tube with a tip is more serviceable.

Taking all these points into consideration, I gradually developed a tube, which in my opinion, embodies all the positive features mentioned above. For a long time I experimented with my tube in order to convince myself of its merits, and now I am ready to present it to the medical profession as an ideal tube for gastric and duodenal intubation.

The tube (Fig. 1, R), is 50 inches in length, and 14 French in diameter, and is semi-soft in consistency, flexible and of good resiliency. Its terminal end encases an elongated drop-shape lead sinker (Fig. 2) narrow and tapered above, but increasing in size at the bottom. The size of the terminal portion of the tube, including the sinker with its layer of rubber is 150 grains in weight, 9/8 inches in length, and 27 French in diameter at the bottom, while at the top, it is the same size as the tube. Two openings slotted in appearance are situated just above the sinker, 1/2 inch apart, on opposite sides of the tube. The diameter of the slots is smaller than the lumen of the tube, thus preventing clogging of the tube by particles of food. The small space between the sinker and the first perforation is filled with rubber.

Upon looking over the literature, I found quite a variation of the markings on the tube. Therefore, to ascertain the exact position of the markings, I fluoroscoped a number of patients after they had swallowed my tube, and I measured the distance from the lips to the cardia. Also, X-ray films were taken after a barium meal, and measurements from the cardia to the pylorus were obtained.

I thus arrived at the average readings for my tube, and placed one mark at 47 cm. or 17 inches from the end of the tube, which represents the distance from the lips to the cardia; two marks at 28 inches, which represents the distance from the mouth to the pylorus, and three marks at 32 inches. However, the physician's

judgment should always determine the amount of tubing for each individual, and he should not rely entirely on the markings.

Advantages:

1. The fear that the patient usually experiences as regards the possibility of the metal bucket becoming detached is eliminated, as the lead dropper is encased in the tube.

2. Swallowing of the tube is accelerated because of the weight of the dropper, which is sufficient to permit its passage through the esophagus with no discomfort to the patient.

3. The tube maintains its intended course along the stomach pathway because of its weight which is 150 grains, its proper arrangement, the lead sinker being so constructed that the lower part is 3 times heavier than the upper part which aids it in travelling along the small curvature and keeps it in the proper place in its progress through the pyloric opening.

4. There is no likelihood of regurgitation of the bucket from the duodenum into the stomach, as is usually the case with other tips, because of the special distribution of the weight of the sinker, which anchors the tube securely in the duodenum.

5. No discomfort is encountered at the glottis upon the removal of the tube, because of its tapered shape and the gradual decrease in size at the neck.

6. There is no need for silver or gold-plating the metal bucket to avoid impairing the mucous membrane, as the sinker is encased in rubber.

7. The openings of the tube have rubber margins, and there is no possibility of cutting the mucous membrane upon suction, as is usual with metal buckets.

8. The openings are slotted, elongated and smaller in diameter than the lumen, and offer a large drainage area, at the same time preventing clogging of the tube with particles of food.

9. A continuous flow is offered through the openings, due to the special arrangement of its lower end, the sinker being 27 French in diameter, while the tube is only 12 French, thus forming an arc which prevents its adherence to the visceral wall.

The Gastric 'Relief' in Duodenal Ulcer: An Accessory Aid in Diagnosis

By

JACOB BUCKSTEIN, M.D.
NEW YORK, NEW YORK

ALTHOUGH Holzknacht (1) and others observed the appearance of the gastric mucosa, incidental to the roentgenologic study of the stomach, it was not until von Elischer (2) that a definite effort was made by a specific technique to roentgenologically demonstrate the rugal folds of the stomach.

The method he recommended consisted of the administration of 75 grams of zirconium oxide with 30-40 c.c. mucilage gum arabic. About 30-40 c.c. of this emulsion was given to an individual on an empty

tion of Forsell in 1913 (3). In this work, he first brought to our attention his conception of the changing nature of the gastric mucosa as conditioned by the intrinsic motor function of the muscularis mucosa. This idea has been elaborated by him in many important contributions which followed.

Schwarz (4) in 1916 showed the importance of a study of the gastric rugae in chronic gastritis, by demonstrating that the prominences in the roentgen picture of the stomach corresponded to swollen hyper-

Fig. 1. A normal 'relief picture' of the gastric mucosa.

stomach by means of a stomach tube. A moderate amount of air was then introduced. The patient was then alternately placed in a horizontal and lateral position in order to produce a uniform distribution of the emulsion over the internal surface of the stomach, thereby bringing out the fine detail of the mucosal folds. After a few minutes the patient was studied roentgenologically, the examination being repeated two or three times at intervals of a few minutes.

Further impetus was given to the roentgenologic study of the gastric mucosa by the classical contribu-

Fig. 2. The gastric 'relief' in a case of duodenal ulcer. Note the exaggerated prominence of the rugal fold.

emic folds of mucosa protruding into the lumen of the stomach.

Eisler and Lenk (5) were able to successfully study the gastric rugae by employing an aqueous suspension of barium which they distributed by palpation over the stomach, and were apparently the first to describe the phenomenon of the radiating convergence of mucosal folds at the site of the niche of a peptic ulcer.

From the standpoint of technical advance in the roentgenological study of the mucous membrane, we are indebted to the work of Akerlund (6) and Berg-

*Visiting Roentgenologist (Alimentary Tract Division) Bellevue Hospital, New York, N. Y.
Submitted August 20, 1957

Fig. 3. Another example of thickening and tortuosity of the rugal folds of the stomach in a case of duodenal ulcer.

mann (7) who by popularizing the method of graded compression, brought more clearly to our attention the variations in the roentgen appearance of the mucosal structure in health and disease.

Rendich (8) in this country did pioneer work in emphasizing the importance of specific attempts to bring the gastric mucosa into clear relief for more detailed study.

The value of the roentgen demonstration of changes produced by chronic gastritis has been verified by Gutzeit (9), Velde (10), Baensch (11), Chaoul (12), Hecker and Prevot (13), and Cole (14).

Pathologically the relation of inflammatory gastric changes to ulcer had been recognized by Cruveilhier. In 1897, Nauwerk (15) claimed that chronic gastritis played an etiological role in ulcer. Similarly Konjetzny (16), Kalima (17), Puhl (18), and others have demonstrated the existence of inflammatory mucosal changes in relation to peptic ulcer.

Faber (19) in the Schorstein lecture delivered at the London Hospital Medical College on May 20, 1927, stated, "We realize then, that the very oldest hypothesis advanced by Cruveilhier, is once more coming in the front—that it is in the gastritis we must seek the origin of the chronic ulcer. Gastritis is likely to assume that predominant position in the pathology of the stomach which has been assigned to it from time to time in the past, only to be subordinated to the theory of nervous, functional disturbance and chronic simple ulcer."

Anderson (20) showed the close clinical and path-

ological relationship of gastro-duodenitis to ulcer, and called attention to the value of the roentgen method of demonstrating its presence.

Thus there appears to be not only a close relationship between peptic ulcer and pathologic evidence of chronic gastritis at least in some cases, but in addition there is substantial and apparently reliable evidence to justify the assumption that such inflammatory changes may frequently be recognized in the roentgenogram.

It is surprising with what frequency one may recognize roentgenologic evidence of thickening and distortion of the mucosal folds in cases of peptic ulcer. Even where the lesion is a post-pyloric (duodenal) ulcer swollen tortuous gastric folds showing marked deviation from the normal may be readily demonstrated. So frequent in fact is this association, that it has been possible in many cases to predict from the roentgenologic appearance of the gastric mucosa that a duodenal ulcer would be discovered. In borderline cases where the direct evidence of ulcer was not altogether definite, we have learned to consider a characteristic gastric 'relief' as strong presumptive evidence of the existence of ulcer. Where the question of the advisability of further check-up study has arisen, we have been definitely influenced in its favor, by such roentgen evidence of thickening and distortion of the rugal folds of the stomach. Because of this close association of peptic ulcer and the characteristic mucosal relief picture, we believe that this finding may be justifiably considered as important 'indirect' evidence in establishing the diagnosis of peptic ulcer. A similar gastric appearance may to be sure,

Fig. 4. Tortuous and prominent mucosal folds of the stomach associated with duodenal ulcer.

Fig. 5. Tortuous and prominent mucosal folds of the stomach associated with duodenal ulcer.

be found in the absence of any of the direct manifestations of ulcer, and apparently as the roentgen counterpart of a chronic gastritis without ulcer. In many cases, however, roentgen evidence of an ulcer has been found in association with this gastric relief.

The causal relationship of the roentgen appearance of the gastric mucosa and the presence of ulcer, particularly duodenal, is not altogether clear. In some cases perhaps there is an actual gastritis which provides fertile soil for the development of ulcer. On the other hand the presence of a peptic lesion may possibly secondarily lead to oedema and swelling of the gastric folds. Whatever the etiological relationship may be, their close association is both interesting and important.

In studying the mucosal relief we have used a simple mixture of barium and water in approximately equal amounts. We feel that the more aqueous the solution the greater the opportunity for its entering all the recesses in a homogeneous manner. The suspension is spread over the mucosa manually. Films are taken in the prone position and a number of exposures are made. These are developed immediately, and further films are taken if necessary. No compression apparatus is employed. While the beauty and diagnostic value of many of the films obtained by special compression technique are unquestioned, it is at best a time consuming procedure. In an institution such as Bellevue Hospital where as many as thirty to forty new stomach cases may be radiographed in a single afternoon, so time consuming a procedure as the technique of graded compression is hardly practical. Even if each examination took only fifteen minutes, eight to ten hours of continuous labor would

be required without cessation or any form of interruption. Moreover it is our experience that even where suspicion on fluoroscopic examination may center on a single area, it may not be safe to neglect the taking of films of the rest of the stomach and duodenum. It is not unjustifiable to state, I believe, that even the most experienced and skillful fluoroscopist may at times fail to note a lesion which he later recognizes in the films. Presumably then, the ideal technique of taking small films of various areas with graded compression under fluoroscopic control, should theoretically include every part of the stomach and duodenum. By centering on one area to the exclusion of others, a lesion may occasionally be overlooked in the region that is not specifically under observation. To make a study of such ideal nature would considerably increase the time required. In addition the amount of exposure to the operator would be enormous.

The routine procedure as employed at Bellevue Hospital is as follows. Under fluoroscopic control the patient swallows a mouthful of a suspension of equal parts of barium and water. The gastro-duodenal mucosa is 'whitewashed' with this mixture. More of the suspension is administered depending on the amount required to visualize the mucosa with manual compression. Films may then be taken in the prone position. Or if a contour study of the stomach and duodenum is made after the more liberal administration of the barium suspension, then in addition to immediate films, a film may be taken every ten minutes as the stomach empties. Such films may be developed promptly to determine the appearance of the gastro-duodenal mucosa during the course of the examination. The Bucky diaphragm may be used to advantage in bringing out the finer detail of mucosal structure.

The fluoroscopic examinations are made in one room, and each patient on completion of this study passes through a revolving door into the next room where films are taken by a technician. Details as to the position of the patient and the number of films desired are put down on a sheet on which are recorded the findings of the fluoroscopist, who may uninterruptedly continue the examination of his many patients. Not only is such a procedure necessitated by the practical problem of examining large numbers of patients in a comparatively short time, but it is

Fig. 6. Gastric relief showing prominent moderately tortuous rugal folds in a case of duodenal ulcer.

very doubtful if the accuracy of the results suffers from the failure to employ the technique of graded compression. Careful fluoroscopy with manual palpation to visualize the gastro-duodenal mucosa, as many films in various positions as may be deemed essential, a detailed comparison of the fluoroscopic and radiographic findings after the films have been developed, and a liberal use of check-up examinations where the slightest failure of complete correlation arises, all combine to reduce the possibility of error.

Whatever may be said in favor of the method of graded compression when used in a small institution with only a few cases a day, there are serious objections to its routine employment in a large institution.

There is also the possibility that the roentgen appearance of the gastro-duodenal mucosa obtained without artificial compression may more nearly approach its real structural nature. It is not at all unlikely that compression under certain conditions par-

ticularly in the hands of the less skilled may produce at times an appearance of puckering which is entirely artificial and at other times produce an obliteration of normal markings by compression even moderately in excess of the optimum.

Examples are included of the thickened tortuous rugal folds so frequently found with duodenal ulcer, as obtained by the simple technique as described above.

SUMMARY

1. A historical survey is presented of the subject of the roentgen demonstration of the gastric mucosa.

2. A simple technique is described for the demonstration of the gastric mucosa particularly applicable to the examination of large numbers of patients.

3. Thickening and tortuosity of the mucosal folds is a common finding in association with duodenal ulcer and may be considered as an accessory diagnostic aid.

Effect of Introducing Oxygen into the Isolated Colon of a Patient with Chronic Ulcerative Colitis*

By

G. M. DACK, M.D.

and

LESTER R. DRAGSTEDT, M.D.

CHICAGO, ILLINOIS

IN 1931 Felsen (1) reported that the repeated introduction of oxygen into the colon was of definite value in the treatment of chronic ulcerative colitis. This observation was confirmed by Golob (2) who recorded a case of chronic ulcerative colitis following amebiasis in which a spectacular improvement followed a course of colonic oxygenation. These observations appeared to us to have a special significance in view of our finding of the almost constant association of *Bacterium necrophorum* with cases of chronic ulcerative colitis in man and the exceeding sensitivity of this organism to oxygen (3).

During the past year Fry and one of us (4) found

that the insufflation of oxygen into the isolated colon of a normal dog into which a human strain of *Bacterium necrophorum* had been introduced caused the rapid disappearance of this organism. In view of this result and because of the favorable reports of Felsen and Golob it seemed advisable to us to determine the effect of the introduction of oxygen into the colon on *Bacterium necrophorum* naturally occurring in cases of chronic ulcerative colitis. In a previous study we have reported that the establishment of an end-ileostomy in patients with chronic ulcerative colitis leads to a simplification of the colonic flora, the exogenous bacteria accompanying the fecal stream disappear, and there develops a predominance of anaerobic organisms, of which *Bacterium necrophorum* has been found

* (From the Departments of Hygiene and Bacteriology and Surgery, The University of Chicago). This study was aided by a grant from the American Medical Association. Submitted August 13, 1937.

to be the most common (5). In our somewhat limited experience end-ileostomy was found to produce considerable clinical improvement, but in no case did the diseased colon become entirely healed. Recurring exacerbations of the disease were observed from time to time with proctoscopic evidence of alternating healing and recurrence of the typical lesions and these were associated with the disappearance and reappearance of *Bacterium necrophorum*.

The patient observed in this study has been referred to as Mrs. N. or Patient No. 1 in a previous report (6). This was a case of typical severe chronic ulcerative colitis on whom an end-ileostomy was performed in April, 1933. Following the operation the patient improved decidedly and gained considerable weight. One year later she gave birth to a normal healthy child. During the period of pregnancy the physical condition of the patient was much improved and proctoscopic examination disclosed also a comparable improvement in the colon. Following delivery the diseased process became worse and since this time there have been alternating periods of improvement and recurrence. On January 29, 1937, she was admitted to the hospital for the present study. At this time the process was quite active and the patient stated that the colon discharges, which numbered 6 to 8 per day, were blood-tinged and contained considerable mucus. Oxygen was introduced into the isolated colon through a long sterilized rubber catheter which was inserted into the rectum for a distance of about 30 cm. The oxygen was obtained from a large tank equipped with a metal valve control. The gas was bubbled through water in order to estimate the volume used. A manometer was attached by means of a side arm to the gas line to prevent the pressure from exceeding 4 or 5 mm. of mercury.

Treatment by means of this oxygen insufflation was begun on February 5th and continued to May 27th, a period of 112 days. During this time the patient received oxygen insufflation on 78 days and no treatment on 34 days. The length of each treatment varied from 2 to 12 hours. Altogether oxygen insufflation into the colon was administered for 460 hours with no interval between treatments exceeding 4 days. The patient was ambulatory except for the period of the oxygen insufflation. During the course of the treatment her general condition improved and there was some increase in weight. Weekly proctoscopic examinations during the entire period revealed alternating improvement and exacerbation of the diseased process. Cultures were taken from the colon three times each week, once from the bowel wall at the time of the proctoscopic examination and twice from discharges collected through a sterile rubber tube inserted into the rectum. In all 43 bacteriological examinations were made. Eosin methylene blue plates and blood agar plates were streaked with the specimens. The eosin methylene blue plates were incubated aerobically for 24 hours at 37 degrees Centigrade. When the colon discharges were bloody there was often no growth on these aerobic plates. During short periods of improvement large numbers of *Proteus* colonies appeared. At no time were typhoid, salmonella, or dysentery bacilli detected. Aerobic and anaerobic blood agar plates were streaked at the same time and the anaerobic plates were incubated under conditions which have been previously described (7). Although the colon was

entirely isolated its bacterial flora varied considerably from time to time. *Bacterium necrophorum* was found in 27 of 43 examinations and was the predominant organism 8 times. It was almost invariably found in large numbers whenever the diseased bowel became worse and more blood appeared in the rectal discharges. A small black colony was often seen on the anaerobic blood agar plates. This colony was encountered in 23 of 43 examinations and on 7 occasions it was the predominant organism. It proved to be a coccus and has frequently been observed in the examination of normal stools. In 18 of the 43 examinations there appeared on the anaerobic blood agar plates colonies which displayed a green zone of hemolysis. These were for the most part Gram-negative cocci, although some were Gram-variable. A smooth white non-hemolytic colony was also found on the aerobic and anaerobic blood agar plates. This was a Gram-negative rod, was found 28 times, and proved to be the predominant organism on 10 examinations. It was representative of the colon group of the Gram-negative bacteria.

Since insufflation of the colon with oxygen failed to improve the diseased intestine and likewise failed to free it from *Bacterium necrophorum*, the question arose as to whether such treatment might give rise to strains of *Bacterium necrophorum* which were resistant to oxygen. This hypothesis was tested by exposing 7 pure cultures of *Bacterium necrophorum* to atmospheric oxygen and subsequently testing their viability. The strains used were isolated from the diseased colon at wide intervals during the course of the oxygen therapy. They were streaked on duplicate blood agar plates and incubated for 4 days under anaerobic conditions. Following incubation the plates were exposed to the air. At 30-minute intervals four colonies were picked and placed into freshly boiled and cooled Rosenow's dextrose brain medium to test for viability. The test was continued for a period of five hours. Growth regularly occurred in cultures exposed to the air up to 1½ hours and irregularly in some of the tubes up to 3 hours, but from 3 hours on to the end of the test period no growth was observed. There was no evidence that strains isolated during the later part of the oxygen treatment were more resistant to oxygen than strains isolated before the treatment was instituted.

DISCUSSION

The significance of *Bacterium necrophorum* in chronic ulcerative colitis remains difficult to evaluate. Further study has always revealed the presence of this organism in the colon in typical cases of the disease, but we have been unable to reproduce the process in experimental animals with pure cultures of *Bacterium necrophorum*. The long continued insufflation of oxygen into the colon in this patient did not bring about the improvement reported by some other observers. Nor did the treatment cause a disappearance of *Bacterium necrophorum* or greatly decrease the number of these organisms. The fact that *Bacterium necrophorum* introduced into the normal colon of the dog is readily destroyed by oxygen insufflation indicates that in the diseased bowel there must be a protective mechanism operating. This persistence is apparently not due to the development of a tolerance to oxygen, but may depend upon the presence of the organism in the deeper layers of the intestinal wall.

It should be emphasized, however, that the failure of colonic oxygenation in this one chronic case should not discourage further trial of the treatment, which may be more effective in the early and more acute phases of the disease.

SUMMARY

Oxygen gas was repeatedly insufflated into the isolated colon of a patient with severe chronic ulcerative colitis. The treatment was given for periods varying from 2 to 12 hours over a time interval of 112 days. During this time 43 bacteriological examinations were made of the colon and its discharges. The isolated dis-

eased colon failed to heal and *Bacterium necrophorum* continued present and was found in abundance, especially during periods when the diseased process appeared aggravated.

The Effect of Orange Juice on Gastric Acidity*

By

CHARLES DIMMLER, Jr., A.B.,

Voluntary assistant in biochemistry under direction of

MARSCHELLE H. POWER, Ph.D.

With an introductory note by

WALTER C. ALVAREZ, M.D.†

ROCHESTER, MINNESOTA

THIS short communication, based as it is on but a limited number of experiments, obviously cannot be regarded as settling anything, but the results of the work were so clear-cut and so according to what any chemist would have expected, that I believe the paper well warrants publication and also attention from gastro-enterologists everywhere. So far as I know it is the only answer we have to a question the great importance of which is just now becoming apparent. The paper will serve well if only it stimulates other investigators to confirm or disprove the conclusions now reached. Naturally the final answer to the question must come from studying the changes in the pH following the giving of fruit juices to many patients with ulcer.

W. C. A.

Opinions among gastro-enterologists differ as to the advisability of including orange juice in the diet of patients who have peptic ulcer. Some withhold it because they fear that it will increase the acidity of the gastric content; some doubt if it contains enough acid to do any harm, while others feel that it is so important to supply vitamin C to patients who are to live for some time on little besides milk that if there is any doubt about the matter it would be best to err on the side of giving fruit juices. Recently Rivers and Carlson and Alvarez and others have pointed out that patients who for a long time are on a strict ulcer diet are likely to have less than the minimal requirement of vitamin C in the blood, and it may well be that incipient scurvy sometimes accounts for the tendency to hematemesis seen in cases of peptic ulcer.

In order to determine the effects of orange juice on the pH of gastric juice, the following investigations were made. Orange juice was prepared freshly each

day. It was filtered and the pH was determined with a glass electrode in an amplified system. The apparatus and its use have been described by Dill, Daly and Forbes. The pH was chosen for study because peptic activity depends on the hydrogen ion concentration and not on the "free acidity." The latter is a vague term which does not mean much to a chemist.

The pH of the six samples of mixed orange juice (from several oranges) used in these investigations varied from 3.63 to 3.99. The oranges used by Kugel-mass in his study must have been more sour than those used in our work, since the juice from them had a pH ranging about 3.0. Kugelmass found that orange juice contains only small amounts of free acid, and that it is really a buffer solution made up mainly of the primary, secondary and tertiary salts of citric acid.

Gastric juice was obtained from patients one hour after they had taken an Ewald type of meal consisting of six arrowroot cookies and 400 c.c. of water. Table I shows that the pH of twenty-seven samples of gastric juice varied from 1.12 to 7.07, with a mode about 1.6. Incubation of the juice at 37° C. for from one to six hours did not change the pH.

After determining the pH of pairs of samples of orange juice and gastric juice, these samples were mixed and the pH of the mixture was measured. A mixture of one part of orange juice to four of gastric juice was chosen because it was felt that a person would seldom take so much orange juice at a meal as to produce in the stomach a richer mixture than this. Table I shows that in the twenty-seven observations the pH of the mixture varied from 1.30 to 4.60, with a mode at 2.1. As one might have expected, the addition of orange juice lowered high gastric acidities and raised low gastric acidities.

In order to get some idea of the change in acidity

*I wish to thank Miss Catherine Sawyer for help which made this work possible.
Division of Medicine, The Mayo Clinic.

which might be produced in the stomach by digestion of the mixture of orange juice and food, the pH of each mixture of orange juice and gastric juice was measured after incubation at 37° C. for periods varying, in different observations, from one to six hours.

TABLE I

The pH of gastric juice, of orange juice and of a mixture of the two

Fresh			Incubated		
Gastric Juice	Orange Juice	Gastric Juice and Orange Juice	Gastric Juice	Orange Juice	Gastric Juice and Orange Juice
1.58	3.78	2.09	1.62	3.76	2.08
1.89		2.78	1.80		2.67
1.25		1.48	1.27		1.52
1.53	3.99	1.93	1.56	3.90	1.96
1.58		2.09	1.62		2.12
7.07		4.37			
6.42		4.42			
3.57		3.77	3.62		
2.08		2.99	2.16		2.99
1.41		1.72	1.46		1.76
1.40		1.76	1.44		1.78
6.26		4.60			
2.58	3.76	3.12	2.57	3.74	3.12
1.12		1.30	1.09		1.31
1.49		1.82	1.47		1.85
2.04		2.68	2.03		2.70
1.29		1.49	1.23		1.49
1.55		1.96	1.55		1.94
1.35	3.72	1.69			
1.30		1.68			
1.87		2.59			
1.66		2.01			
2.42		3.08			
1.63		1.86			
2.18		2.95			
1.26	3.63	1.58			
5.22	3.90	4.30	5.46	3.92	4.33

In no instance was any change in the pH observed.

In order to see what actually happens in a stomach when the juice of two and a half oranges is added to an ordinary American breakfast, two observations were made on healthy persons. For purposes of control, on the first day the volunteers ate a breakfast consisting of three tablespoonfuls of oatmeal, with cream and sugar, two slices of buttered toast, one soft-boiled egg, and one cup of coffee with cream. One and a quarter and two and a quarter hours after the meal, samples of gastric content were removed and the pH was determined. The following day a breakfast identical in quality and quantity to that eaten on the first day was consumed, together with 150 c.c. of orange juice. The data presented in Table II indicate

that in both of these observations the addition of orange juice did not have any effect on the pH of the gastric content.

DISCUSSION

The essential fact which emerges from that part of the study which was carried out in vitro is that, just

TABLE II

The lack of effect on pH when orange juice is added to a meal

Hours After Meal	Subject 1		Subject 2	
	Breakfast Alone	Breakfast with Orange Juice	Breakfast Alone	Breakfast with Orange Juice
1¼	1.65	1.60	2.04	2.27
2½	1.37	1.48	1.88	2.07

as one would expect, orange juice raised the pH or lowered the acidity of every gastric juice of which the pH was below that of orange juice, which, as will be remembered, was around 3.8. Since the pH of gastric juice from normal persons usually is below this level, one must conclude from the observations in vitro that normally the giving of orange juice should lower gastric acidity. Since patients who have peptic ulcer usually secrete gastric juice of which the pH is even lower than that of normal persons, one would expect the addition of orange juice to their diet to lower gastric acidity.

Unfortunately, the time available for this study did not permit more observations in vivo. In the two observations made, the addition of orange juice to the breakfast appeared to have no effect on the pH of the gastric content. This may have been due to the well-known fact that fluids tend to run out of the stomach rapidly, leaving solids behind. This is particularly true when the liquid is taken first on an empty stomach, as orange juice so often is taken in the morning. This point must be kept in mind in any study of the effect of a liquid on gastric acidity. The probability is that it will not stay in the stomach long enough to mix with the gastric secretion, and any effect it may have on the secretion will have to come from effects on the gastric glands, produced as the liquid is absorbed from the small bowel.

CONCLUSION

Judging from some observations made in vitro it seems probable that one need not worry about giving orange juice to patients who have peptic ulcer. If the orange juice should remain in the stomach long enough to have any effect on the acidity of the gastric content, this effect almost certainly would have to be a lowering one because orange juice is considerably less acid than is even normal gastric juice.

Protamine Insulin and the High Carbohydrate-Low Fat Diet in Diabetes Mellitus*

By

SEALE HARRIS, M.D.

and

SEALE HARRIS, Jr., M.D.

BIRMINGHAM, ALABAMA

TWO very great advances have been made in diabetic therapy since Banting's epoch making discovery of insulin in 1922 that make it a joy to treat diabetes mellitus, when one is dealing with an intelligent, cooperative patient. Protamine insulin simplifies the treatment in that the average diabetic can give himself one dose of insulin each morning after he has examined his night and morning specimens of urine; and with the use of the high carbohydrate-low fat diet there is no longer any need for diabetics to endure the pangs of hunger.

Protamine insulin is simply insulin to which has been added zinc protamine in order to make the insulin less soluble so that it will be more slowly absorbed, and therefore its effect more prolonged. Hagedorn and his associates in Copenhagen demonstrated that the rate of absorption of insulin could be retained and its effect prolonged for at least 24 hours by suspending it in a protamine mixture, thus imitating the normal continuous secretion of insulin by the islands of Langerhans of the pancreas. Leyton in 1929 made an unsuccessful effort to prolong the use of insulin by suspending it in oil, and the Hagedorn group made experiments with a number of substances before they found that a combination of the monoproamines and insulin, forming what they called protamine insulate, would retard the absorption of insulin. At first the buffer solution of protamine was mixed by the patient with regular insulin; but more recent investigations, particularly by Best, Kerr, Campbell and Fletcher in Toronto, it was found that a solution of zinc protamine combined with regular insulin formed a stable compound that can be dispensed in ampules so that one c.c. of zinc protamine insulate contains 40 standardized units of insulin. The zinc protamine insulate is now called protamine insulin.

The work of Hagedorn and his associates has been verified by a number of diabetic clinicians in the United States and Canada, including Joslin, Root, White, Marble and Stotz; Frederiek M. Allen; Smith and Grishaw; Sprague, Blaum, Osterburg, Kepler and Wilder; John; Best, Kerr, Campbell and Fletcher; and Anthony Sindoni, Jr. The clinicians mentioned, and others who have reported studies with protamine insulin, agree that its use in uncomplicated diabetes has many advantages over the regular insulin; and in less than two years it is safe to say that protamine insulin has replaced regular insulin in the vast majority of cases now under treatment by physicians experienced in the management of diabetes mellitus;

though in many cases one or more doses of regular insulin is used in addition to the protamine insulin.

Our experience with about 100 diabetics in private practice, in which we have used protamine insulin during the last 18 months has convinced us of the many advantages of protamine insulin over regular insulin; though in the beginning we were skeptical regarding the enthusiastic claims in some of the early published reports of clinicians. Perhaps a reason for our early skepticism was a severe insulin reaction in a child, whose diabetes was under perfect control by the use of the regular insulin adjusted to a diet adapted to the patient's nutritional needs. Since that time we have not had a severe reaction, though in several cases blood sugar readings in diabetics using protamine insulin have been low. One patient had a morning fasting blood sugar of 25 milligrams per cent, though she felt fairly well. A reduction in the dose of protamine insulin maintained her blood within normal limits, though she at times showed small amounts of sugar in her urine.

The Hagedorn group used the protamine insulin in one dose at night, with an added dose of regular insulin before the morning meal. American clinicians, however, soon learned that with the average case a single morning dose on arising will maintain the patients blood sugar within or near the normal range and prevent glycosuria for from 12 to 24 hours. It is a mistake to claim protamine insulin can maintain a level blood sugar curve throughout the 24 hours; because Harrop, in studying half hour blood sugar readings in a series of cases, showed that they were quite marked fluctuations, more below the normal levels. The writer had the privilege of seeing a number of Harrop's cases in the metabolic wards of Johns Hopkins Hospital in which there were quite low blood sugar levels, yet the patients seemed quite comfortable.

HYPOGLYCEMIC REACTIONS FROM PROTAMINE INSULIN

It seems that the diabetic using protamine insulin can stand hypoglycemia better than when the low blood sugars are induced by overdoses of regular insulin. This phenomenon may be explained by the fact that in induced hyperinsulinism from overdoses of regular insulin the blood sugar fall is more rapid, and therefore the reactions occur more frequently than in the more slowly acting protamine insulin when the patient has time to become adjusted to relatively low blood sugars. This also accounts for the more prolonged reactions when they occur following the use of protamine insulin. Sometimes it is necessary to use large doses of orange juice, honey or corn syrup, or

*Read before the South Mississippi Medical Society at Stafford Springs, Mississippi, Thursday, September 9, 1937.
Submitted October 22, 1937.

dextrose intravenously, repeated every few minutes until the hypoglycemic reactions from protamine insulin subside.

Nausea and vomiting are not frequent in hypoglycemic reactions from regular insulin; but in several of our cases of reactions from protamine insulin

keep a record of the examinations of urine, the amounts of carbohydrates, proteins, and fats used each day, and the amounts of protamine insulin used each day. Many of them have kept their urine sugar free with only one dose of protamine insulin a day. They have been instructed not to increase the pro-

TRIAL DIET NO. I

165 to 175 grams carbohydrate, 60 grams protein, 10 grams fat. Five meals a day, at 7 and 10 a. m.; and 1, 4 and 7 p. m.

nausea and vomiting have been pronounced. The nausea and vomiting have been promptly relieved by the intravenous use of a 50 c.c. ampule of a 50 per cent dextrose solution given slowly, intravenously. In fact we believe that in any case of a hypoglycemic reaction from the use of protamine insulin, that the dextrose should be given intravenously, because in such cases the patient may vomit the soluble carbohydrates when given orally and the reaction continue unless the dextrose is given intravenously.

Early reports on the use of protamine insulin urged the necessity of hospitalizing diabetics when making the change from regular insulin to protamine insulin, or in beginning its use with new patients; but at least three-fourths of our approximately 100 cases in which protamine insulin has been used have been ambulatory patients, and in only one of them has there been a severe reaction.

CHANGING FROM REGULAR TO PROTAMINE INSULIN

Our rule in changing a patient from regular insulin to protamine insulin is to begin with a morning dose of approximately half the total daily amount of regular insulin that the diabetic has been using to keep his urine sugar free, and in addition give about three-fourths the morning dose of regular insulin. The patient is instructed to examine his night and morning specimens of urine, and if sugar is present, to increase the protamine insulin by from 3 to 6 units each day until his urine becomes sugar free; then to reduce the dose of protamine insulin by 5 units, because of the possible cumulative effect of the protamine insulin. The morning dose of regular insulin is omitted when the morning blood sugar is within normal limits, or when the morning specimen of urine is sugar free.

In many cases of intelligent cooperative diabetics who have been controlling their diabetes with regular insulin adjusted to the high carbohydrate-low fat diets they have been accustomed to use in keeping their urine sugar free, the transition is made while they continue their regular work. They are instructed to

take protamine insulin when there was only a small amount of sugar in the urine, that it is better to have a small amount of sugar in one specimen of urine in a day, than to run the risk of a protamine insulin reaction from an increased dose.

The new patient who has not used regular insulin and who has not learned to weigh and measure his food, examine his urine, and give himself insulin when necessary, should be hospitalized for a few days under the observation of a diabetic clinician if possible, until his diet and protamine insulin have been adjusted and the patient can be taught how to care for himself in diabetes. In a small number of our cases it has been necessary to use in addition to the single dose of protamine insulin a small dose of regular insulin at the same time or before the noon or evening meal.

Protamine insulin can never take the place of regular insulin when quick action is desired as in acidosis, with or without coma. After the diacetic acid and acetone have disappeared from the urine and the blood sugar has been reduced practically to normal, the protamine insulin may be begun, to which is added smaller doses of regular insulin for one or two days, when it may be left off, if the patient's urine continues free from acetone and diacetic acid.

The regular insulin is preferable to protamine insulin in preparing diabetics for operation and in caring for them until the surgical hazard is over. If, however, the surgical diabetic is using protamine insulin and is controlling his diabetes, his dose may be reduced by about 20 or 30 per cent, and guarded with dextrose intravenously, if necessary. The regular insulin in appropriate doses may be added in the surgical case, using protamine insulin.

HIGH CARBOHYDRATE-LOW FAT DIETS IN DIABETES MELLITUS

We use a high carbohydrate-low fat diet in at least nine-tenths of our adult diabetics and believe that it has many advantages over the high fat low carbohydrate diet, as formerly used. We have had many adult patients using approximately 300 grams of carbohy-

drate, 75 grams of protein and 50 or 60 grams of fats with sufficient insulin dosage to control their diabetes, and switch them without changing their diet, to the use of protamine insulin, without the slightest trouble. It is important, however, to give three smaller meals with a glass of buttermilk or skimmed milk, an orange,

high carbohydrate-low fat diet overcome the objections offered by Sindoni to using the new insulin with high carbohydrate-low fat diets.

It seems rational in the treatment of diabetes mellitus (hypoinsulinism) to adopt a dietary regimen directed towards increasing insulin production, and in

Medium sized banana, or orange, or glass of buttermilk at bedtime and every 2 or 3 hours if awake at night.

or a banana, or an apple, or bread and honey three hours after breakfast, after the noon meal and at bedtime. High carbohydrate-low fat meals are more rapidly digested, absorbed and metabolized, than those of high fat content when the stomach empties more slowly, hence the necessity of food between meals, at bedtime and every 2 or 3 hours if the patient is awake at night in using protamine insulin with the patient using the high carbohydrate-low fat diets. The frequent feedings in using protamine insulin and the

promoting the storage of glycogen in the liver, thus facilitating carbohydrate metabolism. On such a dietary regime, blood sugar levels are lowered, the severity of the disease is ameliorated, the dangers from complications, such as acidosis, arteriosclerosis and gangrene are decreased.

The metabolism of carbohydrates depends largely upon the amount of insulin in the blood, or the degree of its utilization. The ingestion of sugars and starches stimulate insulin production. The studies of Lennox

seem to show that the larger the quantity of ingested glucose the greater the degree of stimulation of the blood sugar regulating mechanism of the body. He found that the ingestion of 1.5 grams of glucose per

could be no increase in function. Soskin and Campbell, however, have shown that depancreatized dogs, when placed on a pure carbohydrate diet, will improve temporarily and live longer than if placed on a diet

kilo of body weight caused, after the temporary rise, a greater degree of hypoglycemia than 0.75 grams per kilo.

Sweeney, of Dallas, Texas, has demonstrated that diets with high carbohydrate content are followed by lower blood sugar levels, thus increasing sugar tolerance, whereas diets with high fat content cause hyperglycemia and diminished sugar tolerance. If carbohydrates stimulate insulogenesis, it would seem that a high carbohydrate diet would increase the output from a poorly functioning pancreas of the diabetic, unless all the islet cells have been destroyed by a previous disease of the pancreas, when it is obvious that there

containing fats. In other words, a high carbohydrate diet will postpone the acidosis (ketosis) and coma from which depancreatized animals die.

Best, who collaborated with Banting in the discovery of insulin and who succeeded Macleod as Professor of Physiology in the University of Toronto, seems in accord with the theory that the ingestion of carbohydrates stimulate the insulinogenic apparatus. In a recent address Best said: "The evidence seems overwhelming that a rise in sugar content of the blood increases the output of insulin."

Recent results obtained from a high carbohydrate-low calorie diet in diabetes, reported by Sansum

Geyelin and Rabinowitch, seems to show that the insulogenic function of the pancreas may be at least partially restored by resorting to the use of quantities of carbohydrate not dreamed of by clinicians prior to the insulin era in the treatment of diabetes. Certainly such diets increase insulin efficiency so that, according to the experience of a number of clinicians, one unit of insulin will in many cases metabolize two or three times as much carbohydrate on the new diabetic diets as when the same patient was on the low carbohydrate-high fat diet.

Sansum, who in 1926, reported his favorable results from the use of a high carbohydrate and relatively low fat diet, believes that on such a diet there may be actual regeneration of the damaged islands of Langerhans, and he cites Shields Warren and Root as having demonstrated that the islands of Langerhans in diabetics can and do regenerate. The fact that on a higher carbohydrate diet diabetics improve in every way, requiring a lower insulin dosage, Sansum believes is evidence of greater efficiency of the patient's insulogenic apparatus, since on the high carbohydrate-low fat diets many diabetics improve to the extent that they cease to need insulin and can metabolize a normal diet. Sansum suggests that it may be another step towards the curative treatment of diabetes.

Woodyatt doubts the theory that the high carbohydrate-low fat diets actually cause a regeneration of the islands of Langerhans. He is of the opinion that while it is true that on the high carbohydrate-low fat diet no more insulin may be required to keep the diabetic's urine sugar free and his blood sugar normal than when he was taking one-half of the carbohydrates and a high fat diet, he cannot metabolize more calories than when most of his food was made up of fats. Woodyatt suggests that on the high carbohydrate-low fat diets much of the ingested carbohydrate is changed into fat and then oxidized. This observation is important in that it explains the necessity for reducing the fats in using the high carbohydrate diet.

Aldersburg and Porges, in Vienna, no doubt working independently of Sansum, Geyelin and Rabinowitch, have had equally good results with the high carbohydrate-low fat diets. They believe that the value of this diet comes from the fact that there is increased storage of glycogen and decreased deposits of fats in the liver. They claim that carbohydrate metabolism, both of normal individuals and diabetics, is increased when the glycogen deposits of the liver are filled; and that when there is an excess of fat storage in the liver the ability to metabolize sugar is diminished.

While carbohydrates stimulate insulogenesis there is ample evidence to prove that fats depress the function of the islands of Langerhans. Rabinowitch cites Allen as having demonstrated that dogs partially depancreatized, to the border line of diabetes, can be made diabetic on a fat-protein diet. Shepherdson states that blood sugar levels will rise on a low carbohydrate diet. He quotes Weeks, Renner and Wishart as having observed in a study of epileptic patients on high fat diets that in every case they developed hyperglycemia.

If a diet high in carbohydrates tends to lower blood sugar levels, whether by stimulating insulogenesis, or by promoting the deposit of glycogen in the liver, it would seem that we have been wrong in giving our diabetics low carbohydrate-high fat diets, and such

seems to be a fact. Therefore, we should correct our mistakes and reverse the ratio of carbohydrates and fats. Practical experience in the management of diabetes on high carbohydrate-low fat diets over a period of ten years by Geyelin and the excellent results reported by Rabinowitch with his "high carbohydrate-low calorie" diet in more than 1000 cases of diabetes seem to indicate that in diabetes mellitus the ratio of carbohydrates to fats should be between 3 and 4 to 1.

HIGH CARBOHYDRATE-LOW FAT DIETS PREVENT ACIDOSIS AND RETARD ARTERIOSCLEROSIS

In dieting a diabetic there are other equally important considerations besides the effort to stimulate increased insulin production. The question of an adequate, well balanced diet, with the proper mineral and vitamin content is important, likewise the prevention of acidosis and arteriosclerosis should be considered in dieting the diabetic. Certainly a high carbohydrate-low fat diet tends to prevent acidosis. Sansum says that even on a carefully balanced diet over exercise will produce acidosis from imperfect metabolism of the individual's own fat. Therefore, on the high fat diet that we formerly used there was always the tendency to acidosis (ketosis). Unquestionably the high carbohydrate-low fat diet lessens the hazard of acidosis and coma in diabetes.

Arteriosclerosis in the diabetic, resulting in gangrene, coronary disease, nephritis, apoplexy and other complications, is receiving a great deal of attention at this time. Ignatowsky, and other German investigators produced arteriosclerosis in animals by feeding them on high fat diets. They believe that hypercholesterinemia was the cause of the degenerative arterial changes in experimental arteriosclerosis. Joslin and Root and other American investigators, have contributed much to the available knowledge of the incidence of arteriosclerosis in diabetes. Rabinowitch cites Shields Warren as having made the statement that he "had never performed an autopsy on a diabetic of any age who had had diabetes for five years without finding evidences of arteriosclerosis."

Hypercholesterinemia from high fat diets is accepted as an important cause of the degenerative arterial changes in diabetes. Rabinowitch has found that the high cholesterol content of the blood in diabetics is usually reduced to normal by his "high carbohydrate-low calorie" diet. At the meeting of the American College of Physicians in Philadelphia in 1935 he presented a report on the cholesterol content of the blood in diabetics on high carbohydrate-low calorie diets over a period of five years. There was the return to normal cholesterol content of the blood in nearly all the diabetics so treated.

Rabinowitch and his associates in the Montreal General Hospital made careful studies of their diabetics at the beginning of treatment, not only as to the cholesterol content of the blood, but as to clinical evidences of arteriosclerosis. They found from many thousand blood cholesterol determinations that with a few exceptions at the beginning of treatment of their diabetics they had hypercholesterinemia. The cholesterol content of the blood of the diabetics on Rabinowitch's high carbohydrate-high fat diet and insulin, was maintained within the normal limits, whereas the control cases kept on a low carbohydrate-high fat diet continued high.

Clinical studies on the diabetics who had been treated with Rabinowitch's high carbohydrate-low calorie diet and insulin over a period of five years, showed that in younger diabetics they did not have evidences of arteriosclerosis; whereas the control group treated with low carbohydrate-high fat diets

also showed a much lower incidence of acidosis and coma among diabetics on a high carbohydrate-low calorie diet than among those treated with the low carbohydrate-high fat diets. Rabinowitch's studies combined with those of Geyelin, Sansum, Aldersburg and Porges, and others seem to prove conclusively that

Glass of buttermilk or skimmed milk, or medium sized banana or orange at bedtime and every 2 or 3 hours if awake at night

showed high percentage of degenerative arterial changes. In the older diabetics on the high carbohydrate-low calorie diet there was a decreased incidence of cardiac and arterial diseases, including angina pectoris, coronary thrombosis and apoplexy.

Rabinowitch's experience over the five year period

diabetics are happier and more efficient on a high carbohydrate-low fat diet, and that the incidence of the complications of diabetes have been reduced very materially by the change from low carbohydrate-high fat diets to an inverse ratio of carbohydrates to fats.

We are convinced of the soundness of the nutritional

principles upon which the high carbohydrate-low fat diets are based; and our experience with this innovation in diabetic therapy over a three year period has been so pleasing that we have adopted it whenever practicable in uncomplicated diabetes. This does not mean that we use the same diet in every uncomplicated case of diabetes; because no two diabetics present exactly the same problems in nutrition and treatment, and it is just as necessary to prepare a diet suited to the needs of the individual under treatment as when the low carbohydrate-high fat diets were used.

SIMPLIFIED DIETS

We have, however, prepared a series of trial diets which may be used with the average uncomplicated case of diabetes, modifying them to meet the needs of the individual under treatment of diabetes. In order to facilitate their use by the general practitioner, estimates of the quantities of each article of food in household measures have been added.

It is highly desirable for the diabetic to have a few days of preliminary diet before placing him upon his maintenance high carbohydrate-low fat diet. Rabinowitch employs what he calls the "ladder diet" to determine whether or not the patient can be rendered sugar free without insulin. On the first day he gives the patient nothing but water, clear well salted fat free broth, tea and coffee. It seems to me that a day of starvation is unnecessary and that the tolerance of the diabetic can be raised more quickly by giving the soluble carbohydrates for one or two days.

For a number of years when a diabetic with diacetic acid in his urine came in for treatment we have given him, every 2 or 3 hours, on the first day 250 c.c. (8 ounces) of dextrose orangeade. This really delicious drink is prepared as follows: 3 ounces of orange juice and 5 ounces of a 5 per cent dextrose solution. It is given cold or hot. The carbohydrate value is 17 grams so that if it is given every 3 hours from 7:00 a. m. to 7:00 p. m. and every 5 hours if awake at night, it is the equivalent of 90 to 144 grams of carbohydrate the first 24 hours of treatment. In addition 8 ounces (250 c.c.) of water is given one-half hour before the first feeding and every 3 hours (1½ hours after the dextrose orangeade) day and night so that the diabetic with the diacetic acid and sugar will find them disappearing from the urine in 24 hours in many cases of moderately severe diabetes; and in the more severe cases with a tendency to acidosis, diabetics usually will become sugar and diacetic acid free by giving 10 units of insulin before the 7:00 a. m., 1:00 and 7:00 p. m. feedings. If there is the tendency to coma, 5 or 10 units of insulin may be given before the other feedings.

In beginning the treatment of diabetes with the ambulatory patient, on the first day we give what we call Trial Diet No. 1. It consists of five meals, one every 3 hours from 7:00 a. m. to 7:00 p. m., each made up of the following: 1 slice of whole wheat bread ½ inch thick, 1 tablespoonful of strained honey, 8 ounces of churned (fat free) butter milk. The total food value of this diet approximates 165 grams carbohydrates, 60 grams protein and 10 grams of fat. Water is given freely between feedings. In the South where churned buttermilk is in common use, and generally liked, this diet will surprise and delight the diabetic who has

been starved for bread, milk and sweets. If the patient objects to the buttermilk he may have skimmed milk, or if he objects to that, he may be given an orange, apple or banana for each feeding.

If the diabetic's urine becomes sugar free in one or two days, as it usually does in mild cases, no insulin is given, and Trial Diet Number 2 is given. This consists of approximately 200 grams of carbohydrate, 50 grams of protein and 40 grams of fat. If on this diet the diabetic's urine is sugar free, Trial Diet Number 3, consisting of 250 grams of carbohydrate, 65 grams of protein and 40 grams of fat, is given for one or two days. If the urine remains sugar free, Trial Diet No. 4, 300 grams carbohydrate, 80 grams protein and 50 grams of fat, is given. This diet, with food value of about 1950 calories will give the average adult diabetic sufficient food to satisfy his appetite and maintain his normal weight and efficiency.

DIETING UNDERWEIGHT AND OVERWEIGHT DIABETICS

If the underweight mild diabetic does not gain weight on Trial Diet Number 4 his carbohydrates may be increased, giving more bread, potatoes and honey until he is getting approximately 400 grams of carbohydrates a day; and the fats may be increased to 90 grams a day by giving an extra pat of butter at each meal making a total daily food intake of about 2700 calories a day. If the underweight diabetic is a laborer, or if he takes a great deal of exercise, his carbohydrates may be increased to 500 grams and fats to 120 grams, thus giving him about 3400 calories a day. When the underweight diabetic has gained to within 10 per cent of the standard weight, his diet is decreased by cutting down his bread, potatoes and other carbohydrates and reducing his fats by eliminating the pat of butter at each meal, until the physician has worked out the diabetic's maintenance diet, i.e., the amount of food upon which the individual can carry on his work with comfort and maintain a weight of 5 or 10 pounds under the insurance companies' estimates of the optimal weight for his age and height.

If the diabetic is overweight his carbohydrates are decreased by leaving off a slice of bread at each meal and reducing the amount of potatoes, rice and other starchy foods until his carbohydrate intake is about 200 grams per day, and his fats are reduced by taking off one less pat of butter at a meal to about 50 grams a day. He is kept on this low calorie diet until he has decreased in weight until he weighs about 5 or 10 pounds below the standard weight for his height and age. Then his diet is increased to Trial Diet Number 4. This maintenance diet is decreased if there is again the tendency to gain weight.

Rabinowitch insists that on his "high carbohydrate-low calorie diet" the patient should become, and remain 5 to 10 pounds under the normal weight. This he calls "mild undernutrition" a highly desirable state in promoting the health, efficiency and longevity for the diabetic.

Uneducated diabetics should be given diets consisting of foods that they can get at home estimated in household measures, and if they have stamina and character they may get as good results in the management of their malady as if they had gram scales and could calculate their own menus. Poverty and ignorance are not insurmountable handicaps for diabetics;

but with the irresponsible, self indulged diabetic, whether educated or not, the paths of overindulgence "lead but to the grave."

If, after two or three days on Trial Diet Number 1, there is still sugar in the diabetic's urine, he is given from 6 to 12 units of Protamine Insulin at seven a. m., and if in twenty-four hours his urine still contains sugar, the Protamine Insulin is increased to 15 to 21 units. If, in another twenty-four hours the sugar has not disappeared from his urine, 30 to 40 units of Protamine Insulin are given on arising. When one of the three daily specimens has become sugar free the diet is increased to Trial Diet Number 2, and if the sugar returns in the urine, the Protamine Insulin dosage is increased until the urine is sugar free. Then Trial Diet Number 3 is given, and if the sugar reappears in the urine, the Protamine Insulin is increased by three to six units each day until his urine becomes sugar free.

The diet is increased to Trial Diet Number 4 in the same way, increasing the insulin slowly until the urine is sugar free. After the patient's maintenance diet and his Protamine Insulin dosage have been worked out as above described, he is kept on the same diet with the same dose of insulin for several weeks, the effort being to keep the urine sugar free without the patient having insulin reactions. If insulin reactions occur, the Protamine Insulin is reduced or the food increased.

We have switched a number of patients from diets of 150 grams of carbohydrates, 60 grams of protein and 120 to 180 of fat to 300 grams carbohydrates, 60 grams proteins, and 50 grams fat, continuing the same dose of insulin they had been using for months or years; and in a few days they would begin to have hypoglycemic reactions, so that the dose of insulin had to be reduced to 25 to 50 per cent. In some of the mild cases requiring from 15 to 30 units of insulin a day, the insulin has been discontinued entirely. In other words on a diet approximately 250 or 300 grams of carbohydrate a day, less insulin was required than when they were getting less than half the amount of carbohydrates and a high fat diet.

Insulin should never be discontinued except on the advice of a physician who has studied the case and one who is qualified to treat the disease. In such cases the insulin dosage is gradually reduced and, if the sugar does not reappear in the urine, the insulin is discontinued. The patient should be made to realize that he should never over-eat, either of carbohydrates or fats; that a food debauch may break his carbohydrate tolerance and he will then have to use insulin again.

Insulin is not habit forming, but it should not be left off suddenly without at the same time reducing

the diet in proportion to the amount of insulin used. The patient taking insulin should keep on hand an adequate supply, but if he cannot get insulin, he should reduce his food by one-half, or even two-thirds and leave off the fats altogether, because the principal danger from leaving off the insulin suddenly is acidosis, or even coma. It is not altogether the leaving off of the insulin that is harmful, but the greatest danger lies in continuing the extra food that the diabetic cannot metabolize without using insulin.

The millennium for the diabetic has not yet been attained; but with the use of vitamin rich, high carbohydrate-low fat diets adapted to the needs of the individual, and with only a morning dose of Protamine Insulin adjusted to the patient's diet, there is no reason for uncomplicated diabetes to interfere with efficiency or shorten life. It formerly was said "once a diabetic always a diabetic," and undeniably any person who had had diabetes should be careful about his diet for the rest of his life; but what Aldersberg and Porges call "curvative treatment of diabetes mellitus" with the high carbohydrate-low fat diet, enables many persons with uncomplicated diabetes mellitus to live the abundant life without insulin.

Recent experience with Protamine Insulin and the high carbohydrate-low fat diet suggest that the insulogenic apparatus of the diabetic may be restored to practically normal function in some of the mild and moderately severe cases of diabetes. We have had a number of patients who, on a high fat low carbohydrate diet had been taking regular insulin for varying periods—one of them 10 years, but who after a few weeks or months on a high carbohydrate-low fat diet and gradually reduced doses of Protamine Insulin, have been able to maintain normal blood sugar levels and remain aglycosuric without insulin. In the last month we have had four patients who have given up the Protamine Insulin and were living on maintenance diets ranging from 250 to 300 grams of carbohydrate, 60 to 75 grams of protein and 50 to 60 grams of fats.

There is reason to believe that an excess of fats in the diet inhibits insulogenesis and that such diets continued for a long time may lower tolerance permanently; whereas carbohydrates stimulate the secretion of insulin and when diabetics are given a high—but not too high—carbohydrate-low fat diet continued for some time, there are grounds for believing that there may be a permanent increase in sugar tolerance. Certainly practical experience with high carbohydrate-low fat diets and the use of Protamine Insulin has shown that in the mild and moderately severe cases of diabetes there is reasonable hope for an approximate cure.

Hydrophilic Colloidal Diet*

By

F. M. POTTENGER, Jr., M.D.

MONROVIA, CALIFORNIA

HYDROPHILIC COLLOIDAL DIET

HYDROPHILIC colloids form the substratum of all living protoplasm. They possess the property of readily taking up and giving off the substances essential to cell life. Precipitation of the hydrophilic colloids of protoplasm causes cell death.

PHYSIOCHEMICAL CONSIDERATIONS

Man's food in the raw state consists largely of hydrophilic colloids. The heat of cooking on the other hand—to mention only the physiochemical change—precipitates the colloids of our diet. This change in colloidal state alters the hydration capacity of our foods so as to interfere with their ability to absorb digestive juices. The amount of interference depends upon both the degree of thermo-concentration and the specific character of the colloidal medium itself. Certain colloids will withstand more heat than others; for instance, cellulose of vegetable origin and certain pectins will stand a greater temperature without being precipitated than the proteins of animal origin.

Any hydrophilic colloid, be it living protoplasm or a mineral jelly, has a certain hydration capacity under given conditions. By varying the physiochemical conditions surrounding such a colloid, it may be made to expand or contract. In the laboratory the expansion and contraction of colloids can be controlled within set limits at will.

Familiar laboratory experiments dealing with the absorption of chemicals and fluid by hydrophilic colloids are the experiments described by M. H. Fischer

(1). If two gelatin squares of similar weight are immersed in finger bowls, one containing distilled water, the other a solution of hydrochloric acid of 1/100 normal concentration, we find two interesting phenomena. First, the gelatin square in the acid expands at a much greater rate than the square in the water. Second, the solution about the square in the acid medium becomes almost of the same hydrogen ion concentration as distilled water. Now, if the acid solution is made stronger, the gelatin is digested, making a colloidal suspension, and unless too great a concentration of acid is present the acidity of the solution approaches neutrality. On the other hand, gelatin precipitated by heat fails to take up water or acid.

PHYSIOLOGIC APPLICATION

If man did not cook his food, there would be no need for the addition of any hydrophilic colloid to his dietary. Uncooked foods contain sufficient hydrophilic colloid to keep his gastric mucosa in excellent condition. On the other hand, man living largely on cooked foods presents a different problem. Recall the description of the stomach contents so vividly described in medical school days, as consisting of several layers, each layer assuming its position by virtue of its specific gravity; meat first, then vegetables and fruits followed and interspersed by the mashed potatoes, and last the water layer with its scum of fat; and how this was churned around and had poured into it sufficient gastric juices to digest the meal in one and one-half to four hours if all was well. If such gastric contents are removed and examined, the aqueous layer is found to be strongly acid, the degree

*Read at the Thirty-eighth Annual Meeting of the American Therapeutic Society, Atlantic City, June 4-5, 1937.
Submitted August 14, 1937.

differing with the individual. The digestive action takes place between the food particles and the gastric mucosa, which to be sure does not digest itself.

If we give a similar meal to another man, adding to it a hydrophilic colloid of excellent hydration capacity, let us say $\frac{1}{2}$ to 1 ounce of gelatin, a definite change takes place in the contents, and if they are withdrawn for analysis, a gluey mass is recovered. It is not sour as would have been the contents of the stomach which did not contain gelatin; and on the contrary it does not show any acidity till the colloid is broken down. Under these conditions, digestion is quite generally distributed throughout the mass.

The gelatinous mass that results from the ingestion of a prepared hydrophilic colloid such as gelatin is formed more quickly than is the case when such raw foods as fruits and vegetables are used, which must first take up the digestive juices and then be partially digested before the mass develops. Raw meats apparently become gelatinous in less time than vegetables. But, as digestion proceeds, all raw foods become more or less gelatinous before liquification takes place. In case of cooked foods, gastric digestion is also directed toward the liquification of the stomach contents, but it is interfered with by the fact that the heat of cooking has precipitated the colloids.

CHOICE OF HYDROPHILIC COLLOID

The choice of hydrophilic colloids for this purpose is legion. Cactus juice and beet juice are both useful. They are considered excellent feed water compounds by engineers because they keep minerals in solution and prevent scale from forming in steam boilers. They are cheap but not refined. Mucin (2), colloidal aluminum hydroxide (3), agar, the edible sea weeds, and many proprietary preparations, which include certain of the silica jells, mucilaginous substances of vegetable origin, etc., are among colloids that may be used.

Each one of the above mentioned substances has one or more drawbacks. It is either too expensive, it produces toxic effects, it is not readily available, it is bad tasting, has insufficient hydration capacity, or it is indigestible. In my work I have chosen to use gelatin because it possesses none of the above disadvantages. It is non-toxic and has a good hydration capacity. It can be purchased at a reasonable price at any grocery or drug store. It is readily available. It can be served in many tasty ways. One can get it at any hotel or restaurant. It is completely digested. Should a hydrophilic colloid with bulk be needed, an indigestible colloid such as agar may be added.

SELECTION AND PREPARATION OF GELATIN

Just as there are grades of gasoline and flour, so are there grades of gelatin. Roughly in the competitive market the grade and price correspond. Gelatin may be made either by an acid or an alkaline process, and any of the poorer grades of commercial gelatins are either alkaline or acid to taste. The best gelatins are neutral. Gelatin may be bought in sheets, or in granulated form. The latter is more readily soluble. In this discussion it is the plain, unflavored and unsweetened gelatins to which we refer.

When one is to choose between two neutral gelatins of different grades, their adhesive properties serve as the best guide. To test this stickiness, take weighed

samples and place them in different containers of the same shape and size. Add to each weighed sample of gelatin an equal amount of cold water, and allow it to expand for five minutes. The containers with the samples of gelatin to be compared, are immersed to the same depth in boiling water and allowed to remain there until all the gelatin is dissolved. Then remove from the water and allow the mass to stand five minutes to cool. Take in turn a definite amount of each sample between the thumb and forefinger, and compare their stickiness. Wash and dry the hands carefully after testing one sample before testing the next. Though this method is rough, it is accurate enough and one will be surprised to find the difference shown by different samples of gelatin.

PREPARATION OF GELATIN

Gelatin may be served to the patient in many ways. It may be beaten up with an ice-cream-malted milk. Prepared in this way it is somewhat granular. It may be taken from a spoon, dry, and washed down with a liquid, although this is usually a very sticky procedure. It may be mixed with dry or cooked cereals, with vegetables, or many other foods. In my experience, the most satisfactory way to use it is to first dissolve it, by mixing it with cold water allowing it to stand in hot water until dissolved and then adding water and flavoring to make it the proper consistency and to improve its taste. It should be stirred while heating to mix it thoroughly. It may be made in concentrated form and added to soup or bouillon or made into a drink flavored to suit. Often a satisfactory method is to add stock solution made from the unflavored preparation to a little fruit flavored gelatin already sweetened. Cold dishes using the amount of gelatin recommended are too tough to eat. It must be remembered that if it is allowed to dry and adhere to cups and glasses it may break them by the contraction.

AMOUNT OF GELATIN

The amount of gelatin to be prescribed varies with the type of diet used and the purpose for which it is intended. If used in connection with a modified Sippy milk and cream diet using hourly feedings, from 7 a. m. to 7 p. m., gelatin, a dram to the feeding, may be added to the milk to take the place of the alkaline powders. For use with regular meals, $\frac{1}{2}$ to 1 ounce usually suffices for the adult. This is enough to make from two to four pints of dessert.

CLINICAL APPLICATION

The use of a hydrophilic colloid in the dietetic treatment of gastric complaints is frequently sufficient in itself to rectify what are apparently serious conditions. Gelatin may be used in conjunction with almost any diet that the clinician feels is indicated. Its colloidal properties aid the digestion of many foods which cause the patient to suffer from "sour stomach." Even foods to which individuals may be definitely sensitive as proven by the leucopenic index, and elimination diets, frequently may be tolerated with slight discomfort or none at all if gelatin is made a part of the diet. The favorable effect on digestion in the upper portion of the gastro-intestinal tract frequently leads to improvement in patients suffering from spastic colitis. The necessity for pureeing foods may not be found if hydrophilic colloids are added. Even

raw vegetables, green salads and fruits which are usually taboo may often be given to these patients with impunity after a short time.

A hydrophilic colloid diet will often give marked relief in the syndrome of slow digestion, gas formation, relaxed cardia and heartburn in which the burning is due to organic acids instead of an excess of the normal hydrochloric acid which frequently accompanies chronic inflammatory diseases affecting such organs as the heart, lungs, gall bladder and appendix. Here again the colloid may be used either in connection with the patient's regular food or with whatever diet the physician feels is best fitted for the patient.

In children who present problems of growth and development and those who show symptoms of allergy in the bowel, the hydrophilic colloid proves to be of great value. One usually prefers to use it in conjunction with a diet designed for the child's general up-building, although the addition of the colloid to the usual diet may be all that is necessary.

The patient with gastric atony or nervous indigestion who complains of heartburn and vomiting four or five hours after eating is often helped. There is apparently a lessening of the emptying time of the stomach and an improvement in gastric tone. A strict dietary regimen is not as necessary when the colloid is used.

Alcoholic gastritis presents a problem which the stewards of country clubs usually solve with their cannibal sandwiches of raw beef on rye bread. The effect is produced by the hydrophilic colloid of the beef. Gastric lavage, some pill or hot soda water have usually sufficed for the physician. The steward who uses the raw meat sandwich probably never heard of hydrophilic colloids yet he and his kind have handed on from father to son the knowledge that raw beef will meet the condition better than any other remedy. A tasty gelatin drink gives relief and allows the patient to avoid the raw meat which is usually distasteful to his squeamish sensibilities.

Gastritis in other forms can be relieved by the use of milk added to a suitable amount of hot gelatin concentrate, beaten thoroughly and taken before coagulation or setting.

While gastric hemorrhage requires special dietary supervision, that particular type with low acid and no demonstrable ulcer may be treated by substituting gelatin for the alkaline powders of the Sippy diet. The gelatin is given with the milk, and not between feedings. The milk, in order to have the greatest potency of vital elements, should be a green pasture raw milk. As was formerly pointed out by me (4) Pasteurization destroys some of the vital elements of milk. It also materially alters its colloids.

The true gastric or duodenal ulcer patient is of a different type and while some patients, as just mentioned, are frequently included under the general heading of gastric ulcer, they have no ulcer. When gastric ulcer with erosion demonstrable by X-ray is present, an increased gastric acidity is usually present. Formerly, attempts were made to reduce the hyperacidity chemically by the alkaline powders. Of late years, colloids too numerous to mention, such as

mucin, colloidal aluminum hydroxide and powdered okra, having different degrees of hydration capacity, have come into use. Absorption of gastric content by the colloidal mass rather than neutralization is the fundamental aim underlying these treatments. Absorption by the colloids of milk and cream, too, plays a large part in the Sippy diet. Therefore, in substituting gelatin for any of these excellent colloids, such as mucin, one is merely changing the nature of the colloid by replacing an indigestible colloid by a digestible one and also inserting an item of common household usage for an expensive preparation.

The dietary regimen to be followed with these patients depends largely upon the convictions of the practitioner. It usually has been my practice to follow a modified Sippy regimen, eliminating the alkalinizing agents and using gelatin instead.

DISCUSSION

Hydrophilic colloids have a very wide application in the field of dietetics provided a sufficient amount of an article of the proper quality is used. In reference to gelatin, which is discussed in this paper as being one of the most available products, we recognize that we are also dealing with a preparation which is a source of glycine, which, as shown by Brand, et al (5), is a muscle and tissue builder and an energizer of first importance; and that because of these properties it may play a very important role in certain of the chronic illnesses; nevertheless, its physiochemical properties seem to be the factors of most importance in the immediate problems of digestion. Gelatin is largely digested before it leaves the stomach, yet it has a profound effect on the entire gastro-intestinal tract. Exactly why this should be true is somewhat puzzling at first. However, if we consider the effect of unusual irritation upon the nerves of the gastro-intestinal canal, it is rational to think that a less violent and more nearly "normal" digestion above might quiet the activity of the otherwise hyperactive gut. Inasmuch as the same foods which formerly produced irritation may frequently be continued without harm when gelatin is used, the relief to nerve irritation seems to offer a logical explanation. Whether the change, in the lower gastro-intestinal tract, is due to the effect of the gelatin itself, or to a more complete digestion taking place along the entire tract due to physiochemical alteration is not clear.

Both factors are probably important. There is undoubtedly a better assimilation of food as is indicated by the general improvement which takes place in underdeveloped children without following so closely the carefully planned maintenance diets which are so often prescribed. Undernourished adults also respond with increased weight and strength without adding to the total calories of their diet.

SUMMARY

1. Hydrophilic colloids bring about conditions in the stomach during digestion which approach those resulting from the consumption of foods in their natural state.

2. Hydrophilic colloids lessen gastric irritation by

absorbing the digestive secretions of the stomach so that digestion takes place within a mass of food.

3. Gelatin, because of its availability, relatively low cost, non-toxicity, adaptability as an item of dietary and its thorough digestibility becomes an admirable hydrophilic colloid for dietary usage.

4. The amount of gelatin to be used in a given case depends on the patient's needs, but it must be of good quality and sufficient in amount.

5. It has a wide range of usefulness in gastro-

intestinal ailments ranging from the atonic conditions met in the chronic invalid to the irritating condition presented in gastric ulcer.

The Biliary Tract Lesion of Duodenal Ulcer*

By

NORMAN W. ELTON, M.D.
READING, PENNSYLVANIA

DUODENO-BILIARY drainage, since its development by Lyon, has been used as a clinical pathological procedure almost exclusively for the diagnosis of cholecystitis and cholelithiasis. This restriction of the point of view has resulted in a failure to appreciate the usefulness of the procedure in the diagnosis of duodenal ulcer and its associated biliary tract lesions, except in a very limited way.

Because of diagnostic inconsistencies and uncertainties encountered in the interpretation of duodeno-biliary drainage alone, or of fractional gastric analysis alone, because of conflicting cholecystographic findings, and—not least—because of the occasional surgical removal of apparently anatomically normal gall bladders, we have undertaken the performance of duodeno-biliary drainage immediately followed by a complete physiologic fractional gastric analysis on all patients presenting gastric symptoms, who are referred to this laboratory for either of these tests.

The technic consists of: (1) aspiration of the fast-ing gastric contents; (2) passage of the duodenal tube into the duodenal zone; (3) stimulation of the biliary tract by the instillation of olive oil; (4) fractioning of the bile flow so as to obtain the most concentrated bile delivered during the gall bladder response, and at least two identical fractions of liver bile after the gall bladder flow has definitely ended; (5) prolongation of the drainage in order to obtain late sediments, and especially red mucus; (6) withdrawal of the tube to the gastric zone for a two-hour, seven-specimen, physiologic fractional gastric analysis after the ingestion of a simple Ewald test meal of tea and toast; and (7) complete aspiration of the stomach at the end of two hours.

On each bile fraction the quantitative bilirubin is determined, and all sediments are carefully examined microscopically. A search is made for red mucus, which usually may be found readily, floating on the surface of the fractions when present. The stomach specimens are titrated for free and total acidity with Töpfer's reagent and phenolphthalein, and the last specimen (complete aspiration) also is examined for red mucus.

This technic has proven remarkably satisfactory. Much of the success of the procedure may apparently be attributed to the use of olive oil instead of magnesium sulphate as the biliary stimulant. The former, immiscible with the duodenal contents and of low specific gravity, rises without disturbing sediments or the prevailing level of the duodenal fluid as it is instilled. The latter, an aqueous solution of high specific gravity, mixes freely with, and dilutes the duodenal fluid, causing sedimentary material to rise as floccules

TABLE I

high above the bucket of the tube, often, no doubt, to be washed up and over into the jejunum. An additional advantage of using olive oil is that digesting oil, in the form of palmitic acid crystals, may readily be identified microscopically as evidence of the presence of lipase from the pancreas.

Reflux of bile during the gastric analysis may usually be avoided by washing out the duodenum, the tube, and the antrum prior to the ingestion of the test meal.

*From the Departments of Pathology and Gastro-enterology, St. Joseph's Hospital, Reading, Pa., May 6, 1937.
Read before the Sixteenth Annual Meeting of the American Society of Clinical Pathologists, Philadelphia, June 3 to 5, 1937.
Submitted July 13, 1937.

Duodenal ulcer has two commonly associated biliary tract lesions: (1) oleaginous cholangiosis (oleaginous catarrh of the bile ducts); and (2) an atonic gall bladder which fails to yield a shadow in the Graham test, and which often fails to respond to the first duodeno-biliary drainage. Since the bilirubin content of

siphonage, and often to be found in the stomach contents especially after a preliminary duodenal drainage, seems quite diagnostic in itself, and its constancy inspires the greatest respect for borderline free acid curves of the extragastric type derived from the gastric analysis when hyperchlorhydria is not

TABLE II
Grading of gall bladder responses

Maximum bilirubin content of normal liver bile 10 mgms./100 c.c.	
Grade I	11 to 15 mgms./100 c.c.
Grade II	16 to 25 mgms./100 c.c.
Grade III	26 to 45 mgms./100 c.c.
Grade IV	above 45 mgms./100 c.c.
Low grade I. responses may be doubtful. Abnormal liver bile may exhibit a bilirubin content above 10 mgms./100 c.c. when liver function is impaired, as in cholecystitis, or after cholecystectomy.	

normal liver bile, as obtained by duodeno-biliary drainage, does not exceed approximately 10 milligrams per 100 cubic centimeters, the absence of a gall bladder response is indicated by not finding a higher pigment level than this in any fraction. Such a finding will usually agree with a positive cholecystogram, provided that the cholecystogram was made prior to the drainage. Since even one oil drainage may stimulate an atonic gall bladder into subsequent resumption of its concentrating activity, a cholecystogram after a drainage in which no gall bladder response occurred, or a second biliary drainage, may be found to be normal. Oleaginous cholangiosis is readily diagnosed by the heavy sediments of yellow oleaginous substance and the coarse, fragmented, twisted mucus, with which it is often associated. This oleaginous material, clear and bright yellow under the microscope after it laves out from the mucus or forms by the coalescence of myriads of minute droplets, is rich in bilirubin. Oleaginous cholangiosis was first described by Lyon and Swalm in the *Journal of the American Medical Association*, March 17, 1928.

The diagnosis of duodenal ulcer is implied by the curves obtained in a physiologic fractional gastric analysis, and is sustained by the identification of red mucus. This red mucus, often obtained by duodenal

featured, and implies that acid dyskinesia as well as hyperchlorhydria is the outstanding characteristic of the duodenal ulcer diathesis. Achlorhydria is not an infrequent manifestation of acid dyskinesia. More frequently, however, the curves of acid dyskinesia, when hyperchlorhydria is absent, tend to be concave upward from the fasting specimen to the last fraction, or tend to show a sustained progressive increase in free hydrochloric acid throughout the entire interval. In general one can almost state that any curve which is not at its maximum (within normal limits) at the end of the first hour, and followed by a recession, may be regarded with suspicion. Usually there is found either a definite acid dyskinesia with hyperchlorhydria, or red mucus is obtained to establish the diagnosis.

No presumption is intended herein to make any statements about the interpretation of the results of fractional gastric analysis not already clearly defined by Rehfuess, the originator of the method, but it is felt that emphasis is necessary to point out the very material value of such interpretations. So called "normal" composite gastric analysis curves, as exhibited in many text books, are undoubtedly misleading, since many of the individuals tested may belong to the ulcer race with acid dyskinesia antedating their gastric symptoms.

From a clinical point of view this subject is open to a most interesting discussion. In typical repeated attacks of acute cholecystitis or biliary colic little diagnostic difficulty is encountered, and a positive cholecystogram or the exhibition of small calculi in a functioning gall bladder is an almost unnecessary formality prior to cholecystectomy. Biliary drainage offers little of diagnostic or therapeutic value in such cases. Contrary to prevailing opinion, the microscopy of biliary drainage is so meager in advanced chronic cholecystitis that it rarely yields any additional information. Formed calculi in a functioning gall bladder without sedimentary material in the form

of gall paste or gall sand usually contribute nothing to the microscopy. Likewise a non-functioning gall bladder, although rich in tyrosin, cholesterol, or calcium bilirubinate as sedimentary material within its lumen, and severely inflamed in its wall, since it is usually sealed off from the biliary tract by obliteration

of the cystic duct, can contribute nothing to the microscopy of biliary drainage. Patency of the cystic duct in such instances appears as a rare exception. When it is deemed expedient to perform a duodeno-biliary drainage in primary cholecystitis, the chief finding will be the absence of a definite gall bladder response when the bilirubin contents of the fractions are determined, although the occasional output of abnormal liver bile with an elevated bilirubin content may cause confusion when liver function impairment is a concurrent factor.

Since we have been conducting these studies it has been a rather common occurrence to find normal biliary tracts and normal gall bladder function in patients long believed to have chronic cholecystitis, but who exhibit the classical clinical pathological findings of duodenal ulcer. Several diagnoses of chronic appendicitis have paled in the light of similar findings.

It is a matter of considerable importance to the patient that duodenal ulcer not be diagnosed as chronic cholecystitis, for to the average physician the latter diagnosis at once connotes a taboo on fats. Lyon (2) has recently explained the physiologic necessity for the use of fats in the treatment of chronic cholecystitis to preserve the functional capacity of the gall bladder. The generous use of fats in the diet of the ulcer patient with an associated biliary tract lesion is

even more essential, since this type of involvement is often readily corrected in its early stages by such physiological stimulation of the gall bladder and bile ducts. Perhaps one of the chief reasons for the frequent success of the Sippy diet or its modifications is not simply that it provides concentrated nourishment in small frequent doses, but because it is a high fat diet which provides constant stimulation of the biliary tract.

A fat taboo to the ulcer patient often results in a sorry spectacle. The harassed patient, between Scylla and Charybdis, finds that there is not much he can eat which is not immediately prohibited by some solicitous member of his family interpreting his physician's instructions, or which does not in his own experience cause him pain and discomfort. Rarely is he aware that he is distressed by fats until so informed. On the other hand, the ulcer patient, correctly diagnosed, does fairly well so far as his incipient biliary lesion is concerned on the fats provided by a conventional ulcer diet.

The masking of the ulcer syndrome by the superimposed biliary syndrome, often characterized by belching and distressing nausea and vomiting, and not infrequently associated with a positive cholecystogram, is obviously one of the commonest sources of error in gastro-enterological diagnosis. Duodeno-biliary drainage coupled with physiological fractional gastric analysis is indeed a time-consuming procedure when properly performed, but it does replace speculation in many instances, and may serve to prevent the removal of anatomically normal gall bladders and to mitigate the fallacy of the fat taboo.

Studies so far completed would imply that duodenal ulcer is a very widely prevalent disease in individuals of both the leptosomic and the pyknic constitutions, manifested in modes often dissimilar to the well known ulcer syndrome, and may well be the most important predisposing lesion in the development of the intractable late cholecystopathies.

SUMMARY

The differential diagnosis between surgical cholecystitis and duodenal ulcer with an associated oleaginous catarrh of the bile ducts or transient cholecystostony can usually be made by the combination of duodeno-biliary drainage and fractional gastric analysis. Frank cholecystitis or biliary colic, requiring surgical intervention, rarely demand confirmatory studies when the syndrome is known to be classical. Borderline patients, however, with ulcer syndromes masked by a superimposed biliary syndrome require careful studies in order to prevent the non-beneficial removal of anatomically normal gall bladders or the injurious prohibition of fats in their diets.

The diagnosis of duodenal ulcer rests upon the demonstration of acid dyskinesia, with or without hyperchlorhydria, by physiological fractional gastric analysis, and the detection of red mucus from the duodenal or gastric zones. The diagnosis of the associated biliary tract lesion of duodenal ulcer rests upon the identification of oleaginous material, oleaginous mucus, or ~~colored, opalescent~~ fragmented mucus in abundance in the sediments from duodeno-biliary drainage, and on the demonstration of the initial absence of a gall bladder response restored to normal by repeated oil drainages or by an adequate fat diet.

Neglect of the biliary tract lesion of duodenal ulcer, and especially a fat restricted diet, may lead eventually to surgical cholecystitis.

Duodenal ulcer appears to be a widely prevalent disease in individuals of both leptosomic and pyknic types.

DISCUSSION OF TABLES

Table I. Volumetric outputs of olive oil drainages.

This table merely shows the volumetric outputs of olive oil drainages during measured time intervals. No pertinent contrast is implied by comparison of those with and without gall bladder responses. Although the series is relatively small, a number of significant details, as demonstrated in this table and those that follow, have been thoroughly worked out.

Lyon finds that the yield of a satisfactory drainage

be considered to have occurred when, after the instillation of olive oil, more than 10 mgms./100 c.c. are found in one or more consecutive fractions, followed by fractions with levels not above this amount upon the cessation of the gall bladder flow. Fractioning is a simple matter of changing the receiving jars at arbitrary intervals, guided chiefly by the detection of changes in the color density of the outflowing bile. Even when the outflow appears continuously of the same color density it is advisable to change the jars at intervals, for occasionally a gall bladder response will not be apparent by observation alone, but may be detected by the quantitative bilirubin determinations.

In drainages yielding abnormal liver bile it is at times difficult to distinguish a low grade I response (11 to 12.5 mgms./100 c.c.) from abnormal liver bile. Frequently such doubt may be removed by continuing the drainage as long as possible to demonstrate the persisting high bilirubin level of abnormal liver bile and the lack of contrasting elevations in response to oil instillation. Cholecystography may occasionally be necessary under such circumstances. When the gall bladder is known to have been removed, a high bilirubin level is obviously indicative of abnormal liver bile. No evidence has yet been acquired that the ducts, even when dilated, have any concentrative capacity,

should average 300 cubic centimeters in a three-hour interval when magnesium sulphate or peptone are used as the stimulants. Since a considerable portion of this amount may be accounted for by the diluent action of these stimulants, the outputs obtained with olive oil, as shown in this table, may be considered quite adequate in comparison. In computing these volumes all washings have been disregarded, and the top layers of olive oil are likewise not included.

The volume output during a given time interval is not always properly comparable with that of other time intervals, since occasionally a drainage will flow poorly or cease to flow, whereas others will flow so freely that they may have to be discontinued in the midst of the flow, or allowed to continue as long as the patient desires.

Table II. Grading of gall bladder responses.

The terms "grade" or "grading" as used herein do not imply pathology, but, on the contrary, the degree of normality in the sense of physiologic functional capacity on the part of the gall bladder. Upon fractioning the biliary outflow in a series of from four to eight or more receiving jars, and upon the determination of the bilirubin levels of the various fractions, a gall bladder response may

for the abnormal liver bile continues to flow long after sufficient volume has been obtained to evacuate the most sacculated biliary tree.

Since the gall bladder does not always empty completely in response to a single instillation of olive oil, a second rise in the bilirubin level immediately following a repeated instillation may be construed as a gall bladder response.

During the flow of the "B," or gall bladder fraction, liver bile also flows, causing a dilution of the gall bladder bile, so that the bilirubin level of the most concentrated fraction of this portion of the flow cannot be considered to represent the actual concentration existing in the gall bladder itself, but must be considered only as a relative value.

Table III. Grades of gall bladder response in 128 olive oil drainages.

This table demonstrates the relative infrequency of doubtful responses as well as the low incidence of grade I responses. Additional drainages carried out in the warm days of early summer, since the compilation of this table, have shown a rather marked increase in frequency of the very high grade IV responses. This observation may be merely coincidental, or it may imply that the light diet of

warm weather affords little stimulus to the average normal gall bladder, causing higher concentrations to occur.

Table IV. Analysis of the absence of gall bladder responses.

Herein are tabulated the clinical diagnoses associated with failure to obtain gall bladder responses in duodeno-biliary drainage.

Table V. Nature and frequency of the biliary tract lesion of duodenal ulcer.

In this table are tabulated a number of cases in which the diagnosis of duodenal ulcer has been satisfactorily established from a clinical point of view. Confirmatory

these 18 patients may develop severe cholecystopathy in time, although all are now reported doing well on ulcer management and an adequate fat diet.

It is not the intent of this paper to prove that all cases of severe cholecystitis requiring surgical intervention are the result of unrecognized duodenal ulcer, but the more critically one studies this phase of the question the more one is impressed by the fact that this does seem true in a surprisingly large number of such instances. Although this surgical group is not presented here, many of the patients comprising it have presented undeniable evidence of the existence of duodenal ulcer in addition to their pathological gall bladders, and in several the ultimate decision to perform a cholecystectomy matured rapidly following the institution of the fat-free diet.

Table VI. Estimated bilirubin outputs in milligrams per 24 hours.

The figures in this table represent the 24 hour outputs of bilirubin calculated from the amount of the pigment excreted during the measured time intervals of duodeno-biliary drainage. Naturally, when a gall bladder response occurs, the estimate will be appreciably in excess of the physiological 24 hour output, because of the contribution of the gall bladder contents, which is but a transitory factor. However, these figures do imply clearly the actuality of the gall bladder response as contrasted with the estimates obtained from the data on drainages in which the response is lacking.

It is also apparent that when abnormal liver bile is obtained the bilirubin outputs exceed those observed when normal liver bile is obtained. This phenomenon does not necessarily imply an overproduction of the pigment by the hemolytopoietic system, for it is also possible that oil stimulation may evacuate the lobules of a pigment-laden liver quite independently of any such factor as overproduction of the pigment at its source beyond the liver. To elaborate on this point a little further, the following extraordinary finding might well be mentioned. A patient finally found to have duodenal actinomyces had had over an interval of several years an ulcer syndrome, a gall bladder syndrome, an appendectomy, and a cholecystectomy. Neither of the two operations afforded much of any relief. The ray fungus was finally discovered in a duodeno-biliary drainage two years after the removal of a moderately pathological gall bladder. In this drainage the fractions comprising the first 100 cubic centimeters of bile exhibited bilirubin contents of 9 to 10 mgms./100 c.c. The following fractions, comprising another 100 cubic centimeters assayed 18 mgms./100 c.c., and the terminal fraction dropped to 6 mgms./100 c.c. If it were not known that this patient had had his gall bladder removed, these findings would be fairly typical of a delayed grade II gall bladder response. The fact that the first 100 cubic centimeters of bile was sufficient in volume to evacuate whatever might have been in the bile ducts, whether dilated or not, and exhibited a low bilirubin level, seems to imply that the subsequent 100 c.c. must have come from a pigment-laden liver which readily discharged its overload during the period of the drainage. Other explanations of this exceptional finding are theoretically quite admissible.

The 24 hour bilirubin outputs in the absence of a gall bladder response, as shown in this table are somewhat higher than the actual 24 hour outputs obtained by surgical choledochostomy reported in an earlier paper (3), and indicate that, although variable, the average is about 110 milligrams for a human adult.

CHART I

Quantitative bilirubin method for bile [As obtained by duodeno-biliary drainage]

REAGENTS: 1. Ehrlich's diazo reagent 2. 95 per cent ethyl alcohol 3. Cobaltous sulphate bilirubin standard [Same reagents as are used for serum bilirubin]	
PROCEDURE: 1. Place 1 c.c. of bile in common graduated centrifuge tube 2. Add 1.5 c.c. Ehrlich's diazo reagent 3. Fill to 10 c.c. mark with 95 per cent ethyl alcohol and shake (gives clear ruby red solution of azobilirubin) 4. Place some of azobilirubin solution in cup of Duboseq colorimeter and match with cobaltous sulphate standard. Set standard at 5 millimeters. Standard is equivalent to 0.5 milligrams bilirubin per 100 c.c.	
CALCULATION: Bilirubin content in milligrams per 100 c.c.	
$\frac{\text{Reading of standard}}{\text{Reading of unknown}} \times \text{dilution factor} \times (0.5)$	
or	
$\frac{25}{\text{Reading of unknown}}$	

X-ray findings have been reported in many of these, and in each case follow-up histories have substantiated the original findings with a very reasonable degree of accuracy.

Red mucus is usually identified by careful inspection of the duodenal or gastric specimens, and is generally found floating on or near their surfaces. Grossly and under the microscope its color is red or reddish brown. It appears to consist chiefly of a decomposition product of hemoglobin. Sometimes it is manifest as light brownish shreds, difficult to identify grossly, but which stand out prominently by their blue-green color in the benzidine test when the surrounding fluid shows no evidence of the presence of occult blood. It gradually loses its distinctive coloration on standing.

Among the 18 patients exhibiting non-functioning gall bladders only one is known to have undergone cholecystectomy, and then, after the removal of an anatomically normal gall bladder, symptoms persisted until ulcer therapy was instituted. It is conceivable that a number of

Gastric Acidity in Chicks with Experimental Gastric Ulcers*

By

GARNETT CHENEY, M.D.
SAN FRANCISCO, CALIFORNIA

EROSIONS of the gizzard were first described by Dam in 1929 in conjunction with a hemorrhagic dietary deficiency disease in chicks (1), now known as chicken hemophilia. More recently, Almquist and Stokstad (2) have shown that the erosive lesions in the muscular part of the chick's stomach are independent of the hemorrhagic syndrome and can almost constantly be produced by a basal fish meal diet containing the known vitamins, but devoid of alfalfa and grain. The gastric lesions appear in the early weeks of life when the chicks are placed on this diet from the time they are hatched, and may be completely prevented by addition of adequate amounts of alfalfa and hempseed, their extracts, and by a number of other substances. His work also suggests that well established lesions may be cleared up by adding a rich supply of the "anti-gizzard erosion factor."

These same gastric erosions were observed by the author while studying fowl hemophilia (3). Over 200 stomachs have now been examined which show characteristic changes. The most striking of these lesions are single, but they are more commonly multiple, varying from a millimeter to a centimeter in diameter and grossly resembling human gastric ulcers (Fig. 1).

Fig. 1. Gastric ulcers in chicks. Circles indicate location of ulcers. A. Superficial hemorrhagic ulcers. B. Large penetrating ulcer.

Although they are often superficial and have previously been designated as erosions they may involve underlying structures and become chronic. It appears justifiable in accordance with Hurst's view (4), to call all these lesions gastric ulcers. The histo-pathology of these ulcers will be described elsewhere (5). One is struck by the analogy of this disease in chickens to that occurring in humans. The lesions are in the

muscular portion or gizzard which corresponds to the pyloric region of the stomach in man (6), and very rarely occur in the upper glandular portion of the stomach. They are most common where the acid glandular secretion first strikes the distal non-acid producing mucosa which is covered by a firm mucoid secretion in the chickens. They occur in a stomach where muscular activity is normally marked (7). There is gross and microscopic evidence of localized gastritis, and the entire fundus may be involved. Another characteristic and a constant finding in chicks on this basal diet is a loss of muscle substance and tone of the stomach which may reduce its weight to one-half of the expected normal. This occurs whether ulceration is present or not.

With these findings in mind one is naturally curious as to the secretion of acid in the stomach of the chicken. Although it is stated that acid and pepsin are secreted (8), no studies of gastric acidity by modern clinical methods could be found. Consequently a satisfactory technique has been worked out, it having been determined by autopsy studies, that acid is only produced in the glandular portion or fundus and that the secretion of the muscular or pyloric portion is always alkaline.

METHOD OF GASTRIC ANALYSIS

It was found necessary to use an anaesthetic and sodium pentobarbital (Nembutal) was chosen as the most satisfactory one. It was administered intramuscularly in a dose of 48 to 60 mgs. per kilo of body weight. Chicks varied somewhat in their response, the smaller dose not producing sufficient drowsiness, while the larger dose produced exitus in five instances before the test could be completed. Occasionally a second small dose of pentobarbital would have to be given if the first dose was too small. Ideally administering 54 mgs. to a one kilo bird would produce deep sleep for one to three or four hours, permitting very satisfactory study. For intubation, a small rubber catheter perforated at the tip was introduced into the gastric fundus. Numbers 12 and 14 French urethral catheters were found most serviceable for this purpose, although they were barely of sufficient length for the older birds. Their introduction into the stomach proved somewhat difficult at first due to their tendency to curl up in the crop. This difficulty could usually be overcome by turning the bird on its back and stretching out its neck; with practice the procedure became relatively simple. The catheter was fastened to the beak by adhesive to prevent regurgitation of the tube.

The birds were kept fasting 12 to 24 hours, but were usually allowed water freely. Although the fasting contents of autopsied birds almost invariably shows the absence of free HCl, during life free acid is usually present. Routinely the fasting contents were aspi-

Fig. 2. Gastric acidity and volume curves under basal conditions and after histamine injection in a seven months old chicken.

rated over a 10 to 15 minute interval and then histamine was administered intramuscularly in a dose of 0.01 mgs. to birds weighing less than 1 kilo and 0.02 mgs. to birds of 1 kilogram and over. This is comparable to the dosage for man. The histamine solution was freshly made up each day. After the injection of histamine, specimens of the gastric contents were removed at 10 minute intervals for one hour, and their volume, gross characteristics, and free and total acidity recorded. If the stomach was well emptied the gastric juice was opalescent and usually yellowish or greenish due to bile. Occasionally after 40 to 50 minutes there would be an insufficient amount of secretion to examine. Free and total acidity were titrated in the usual manner with Topfer's reagent and phenolphthalein, except smaller volumes of gastric

Fig. 3. Gastric acidity and volume curves after injection of histamine in a four months old chicken with a large gastric ulcer.

Fig. 4. Highest total gastric acidity recorded by months in thirty-eight chickens.

juice had to be employed, usually 1 or 2 e.e. Consequently, 0.01 normal sodium hydroxide was used instead of 0.1 normal. No routine tests were made for pepsin. The birds on the basal diet and most of the normal birds were autopsied after the gastric analysis to determine the presence or absence of gastric lesions.

Gastric secretory findings are surprisingly constant. Repeated studies in three birds showed essentially the same results. Fig. 2 illustrates the acid and volume values for the normal chick. In this experiment the basal secretion was studied at 10 minute intervals for 40 minutes before the injection of histamine. A temporary increase in free and total acidity to 55° and 75° occurred and the 10 minute volume rose to 3.5 c.c. with a subsequent marked drop. After histamine injection the free HCl rose to 110° and the total acidity to 125° in the fourth aspiration and then fell. The 10 minute volume of secretion rose to 3 c.c. and gradually fell to the initial figure. Fig. 3 illustrates the results of a routine gastric analysis in a chick with a large gastric ulcer. The findings are similar except higher acid values were reached and the volume of gastric contents obtained was somewhat greater. The striking similarity of these gastric analysis curves to those obtained on the human patient are obvious.

Gastric acidity studies were carried out on 38 white leghorn chicks† varying in age from 3½ weeks to 7 months. These birds were divided into three groups; those which were considered normal, those on the basal diet which showed ulcerative gastric lesions, and those on the basal diet which showed gastric atony of the gizzard, but no pronounced lesions of its lining.

There were 17 birds in the normal group which were

†I am indebted to Poehlmann's Hatchery in Petaluma, California, for donating all the birds studied.

on a liberal grain and alfalfa diet and which were kept in a large roofed pen out-of-doors. They varied in age from 3 to 7 months. The highest total acidity findings are recorded by age in Fig. 4. The average total acidity for the group was 121.8°, with a variation between 90° and 150°. The acidity was above the average in 7 birds or 41.2%. Sixty minute total volume studies were available in 20 normal birds, an additional three having been added in which exact acid values were not recorded. The average amount of gastric contents obtained in these birds in one hour was 14.1 c.c. with a variation between 8.1 e.e. and 26.3 c.c. The average age for these chicks was 4.6 months.

There were 13 birds in the second or ulcer group and they varied in age from 3½ weeks to 5 months.

Fig. 5. Total hourly volume of gastric contents after histamine injection recorded by months in thirty-seven chickens.

Their experimental basal diet consisted of fish meal 17.5%, brewer's yeast 7.5%, sodium chloride 1%, cod liver oil 1%, and rice flour 73%. These birds were kept in doors in small pens with boarded floors, or cages with screened floors. The acidity values are also recorded in Fig. 4 for comparison with the normals. The average total acidity for this group was 138.6° with a variation between 115° and 160°. The acidity was above the normal averages in the nine instances or 81.8%. Two birds with low acid values are shown in Fig. 4 which are omitted from these averages as they died before their gastric secretory studies could be completed. Volume studies for the group are recorded in Fig. 5. The average of 12 birds for one hour was 15.4 c.c. with a variation between 8.0 e.e. and 25.0 e.e. Sixty minute volume studies could not be completed in one of this group. The average age for the group was 3.5 months.

There were 8 birds in the third group. They received the same experimental diet as the previous group, but failed to show ulcerative lesions at the time of autopsy. The age of these birds was from 3 to six months.

The acidity values shown in Fig. 4 average 114.3° with a variation between 105° and 140°. Two birds or 25% showed acid values above the average normal. The volume of secretion for 5 birds is recorded in Fig.

5 in the same fashion as in the previous groups. The average volume for one hour was 15.0 c.c. with a variation between 7.9 e.e. and 20 c.c. The average age of these birds was 4.8 months.

A comparative analysis of the gastric acidity values for the normal and experimental groups of chickens suggests that chickens with experimental gastric ulcers due to dietary deficiency secrete gastric juice of a higher acid titer than normal birds, and may also secrete larger volumes of this juice. On the average the chicks with ulcers secreted 16.8° higher acid than the normals, and 24.3° higher than the experimental group without ulcers. Or, it may also be stated that only two-fifths of the normal birds had acid values above the average, while the birds with ulcers had four-fifths of their group above the average normal. In the third group, only one-fourth of the chicks had acid volumes above the average. If any variation of acidity with the age of the chick by months can be deduced from Fig. 4, it would seem that the older birds in this series tend to secrete more highly acid juice. As the majority of chicks with ulcers are in the younger age groups, it would make the increased acidity for this group all the more convincing. Comparison of the experimental groups with and without ulcer make the difference even more pronounced particularly as it has been noted that after the first four or eight weeks, chicks on an ulcer producing diet are less likely to show ulcers. Gastric analysis is difficult in chicks under one month of age and no adult chickens have been included in this study, consequently, the relationship of gastric acidity to the age of the developing chick in months and the adult chicken in years must await more extended observations. It is noteworthy that achlorhydria was not encountered in this series of young birds, even though gastritis was pronounced in some cases.

Chicks secrete large volumes of gastric juice as Fig. 5 shows. The ten minute volumes have reached as high as 8 e.c. and the total hour volumes equalled 2% of their total body weight. Although the ulcer group averaged only 1 c.c. more than the normal group per hour, the majority were much smaller birds and averaged a month younger in age than the normals. As it is reasonable to assume that in a large number of observations the relatively small stomach of a young chick will not secrete as large a volume of juice as that of an almost mature bird, this difference is probably real rather than apparent, and indicates that chicks with ulcers have hypersecretion.

As human patients who develop gastric ulcers may show a lower acidity when they are free of the symptoms and signs of ulcer, than when they are ill, the tendency in chicks without ulcers to show a lower acidity than those chicks with ulcers may be comparable. A plausible explanation of this difference in acidity would be that the normal balance between acid and base components of the total gastric secretion is interfered with when the diet is deficient and that instead of there being an excessive amount of acid secreted there is in reality too little alkaline secretion produced. The disorder might then be termed a hypo-alkalinity, rather than a hyperacidity. It is in keeping with the known fact that other factors than hyperacidity are important in producing gastric ulceration, and these chick experiments strongly suggest that

one of these factors, and a major one, is a dietary deficiency of an as yet unidentified substance necessary to the local resistance of the gastric mucosa.

CONCLUSIONS

1. Experimental gastric ulcers may readily be produced in chicks on a deficient diet.

2. Gastric acidity in chickens following histamine injection is comparable to that found in man.

3. Chickens with gastric ulcers have hyperacidity.

4. The increased acidity in chicks with ulcers over those without ulcers suggests that it is a result of whatever causes the lesions and not a direct cause in itself.

5. The cause of the ulcers and the hyperacidity is apparently the lack of a dietary factor which has a specific effect on the resistance of the gastric mucosa.

Some Recent Advances in the Physiology of Gastric Secretion*

By

B. P. BABKIN, M.D., D.Sc., F.R.S.C.
MONTREAL, CANADA

PHYSIOLOGICAL experiment in the field of gastroenterology during the last few years has indisputably shown that the digestive glands are organs of compound structure, composed of different sets of epithelial cells, whose activity is regulated—i.e. stimulated or inhibited—by different nerves or by various hormonal or chemical agents. The secretory work of a gland therefore is not regulated as a whole, but the final product of this activity, namely the glandular secretion, and in particular its composition are dependent on the participation of various mechanisms—nervous or humoral—which stimulate different parts of the gland. It may thus be concluded that the *quantitative* changes which under physiological conditions occur in some of the digestive juices, produced by glands of compound structure, in response to various stimuli are due to unequal *quantitative* activity of different groups of epithelial cells in these glands (Babkin, 1931, 1934). This theory is not inconsistent with two well established facts, *viz.*:

(1) The influence—positive or negative—that one nervous or humoral stimulus, which affects predominantly one group of glandular cells, may exert on another stimulus, which controls some other group of cells, and *vice versa*. The best example of this is the so-called “augmented salivary secretion,” where the preliminary stimulation of a parasympathetic nerve increases the effect produced by subsequent stimulation of the sympathetic nerve.

(2) The alternation in the volume and composition of the secretion that may be brought about by a change in the intensity of stimulation applied to a nerve which acts on only one group of secretory cells. Many examples of this could be quoted. For instance, it is well known that, when the chorda tympani is stimulated with an electrical current of a certain intensity and the intensity of the current is then raised, not only is the volume of the submaxillary secretion

increased, but the saliva is enriched with organic colloidal material and inorganic salts. Again, under vagal stimulation an increase in the volume of the gastric and pancreatic secretions and in their respective enzyme contents is to be noted as a rule on any increase in the strength of the current applied to the vagus nerve. The probable cause of this phenomenon is that the glandular cells which supply the digestive juices with organic colloidal material and enzymes are subject not to the “all or none” law but to some other law (Babkin, 1931; Mansfeld, Hecht and Kovács, 1931).

With particular reference to the gastric mucosa it should be mentioned that, in addition to the fact that it is composed of different structural elements—surface epithelium cells, mucous cells of the neck, peptic cells and parietal cells—the relative numbers of these cells vary in different parts of the fundus and corpus mucosa (Aschoff, 1923). Thus what one may term the “functional topography” of the gastric mucosa must not be overlooked in considering the various ailments of the stomach.

Furthermore, in the region of the lesser curvature (which includes the so-called “Magenstrasse”) the mucous membrane is much thinner than in the fundus and the corpus of the stomach, and it should be noted that this region and also the pyloric region are under much more effective nervous control than the rest of the organ. Thus, according to Schabadash (1930), a section of the gastric wall with a surface of 4 sq. cm. will on the average contain:

In the region of the fundus, 80 to 200 nerve cells.

In the region of the corpus, 250 to 320 nerve cells.

In the region of the pylorus and lesser curvature, 320 to 450 nerve cells. Presumably on account of the abundant nerve supply the secretory activity of a pouch constructed in the region of the lesser curvature is distinctly more under the control of the vagal innervation and less under hormonal control than that of a pouch formed from the gastric wall at the greater curvature (Alley, 1933; Davidov, 1935).

Submitted October 9, 1937.

With these preliminary data in mind we shall discuss some of the problems relating to the function of the gastric mucosa in normal and abnormal conditions. As a result of our own experiments on the dog and cat and on man, and taking into consideration the data obtained by other investigators, we may draw the following conclusions.

(1) It is well known that, while gastric secretion is at its height, there is very little variation in the acidity of the juice and in the concentration of total and of neutral chloride. Towards the end of the secretory period the acidity usually becomes somewhat less, and the concentration of total chloride diminishes, while that of the neutral chloride increases. Several theories have been suggested in explanation of this phenomenon.

According to Pavlov (1910), the small amount of gastric juice of constant acidity which is produced during this period of secretion is neutralized by the alkaline mucus of the surface epithelium. This view has recently been upheld by Webster (1929) and by Bolton and Goodhart (1931). In addition to the neutralizing influence of the gastric mucus, Hollander (1934, 1936) emphasizes the importance of the neutralizing effect of the "alkaline component"—a fluid secreted by cellular groups of the gastric glands other than the parietal cells, which latter always produce a secretion of constant acidity. Hollander supposes that the "alkaline component" is a mixture (isotonic with blood) consisting of neutral chloride and various buffer salts, chiefly bicarbonate; as such it may contain only 350 to 380 mg. per cent (99 to 108 m.eq. per liter) of Cl, whereas the Cl values of the acid gastric juice very often attain a level of 575 to 585 mg. per cent or more (up to 170 m.eq. per liter). He believes that the concentration of total chloride in the gastric juice is not constant but increases with the increase of the acidity. The same relations between the total chloride and the acidity were found by Wein and Frisk (1936) to exist in human gastric juice. Since, as we shall see later, the volume of the "alkaline compound" is small, and its alkalinity very moderate, its effect becomes noticeable only when the secretion of acid has greatly diminished, and results in an increase in the concentration of neutral chloride in the juice. Unfortunately data concerning the actual composition of the "alkaline compound" are lacking. However, a few facts are known regarding the composition of gastric mucus, the source of which is the surface epithelium and perhaps also to some extent the mucous (chief) cells of the neck. According to Bolton and Goodhart (1931), the gastric mucus of the cat under ordinary conditions contains from 0.28 to 0.36 per cent of inorganic chloride. Mucus collected from the entire stomach of a dog by Webster (Ph.D. Thesis, McGill University, 1933—unpublished) contained 471 mg. per cent of total chloride; its alkalinity amounted to 16.8 m.eq. per liter. Gastric mucous secretion obtained on stimulation of the splanchnic nerves in the cat (Baxter, 1934) possessed an alkalinity of from 11.2 to 14.0 m.eq. per liter and a total chloride content of 462 to 510 mg. per cent. The chloride content of gastric mucus in humans averages 100 m.eq. per liter (Wein and Frisk, 1936). It would be of great assistance to the physiologists in determining the composition of the gastric secretion minus the hydrochloric acid, if some of the clinical investigators would analyze the secretion produced by the gastric glands in

cases of achylia gastrica where no hydrochloric acid is being secreted but pepsin is still present in the juice.

According to the above theory, the composition of the principal components of the secretions of various cellular groups of the gastric glands is constant. On the other hand, Rosemann (1907, 1920) and his followers believe that the composition of the gastric juice may vary. In their view the concentration of total chloride in the gastric juice is practically constant, but the intensity of the stimulus determines the distribution of chloride between the hydrochloric acid and the neutral chloride. The stronger the stimulus, the more chloride will be present in the juice in the form of hydrochloric acid and the less in the form of neutral chloride.

It seemed to me (Babkin, 1929) that the variations in the acidity of the gastric juice could be accounted for by abnormally increased secretion of the "chief (or mucous) cells of the neck." These cells are present in the gastric tubules in considerable numbers; they gradually become more numerous towards the pyloric end of the stomach, the number of peptic cells correspondingly diminishing. Therefore the admixture of the secretion of the "chief cells of the neck" to the gastric juice must be substantial. It is quite possible that the glucoprotein present in the gastric juice in soluble form (so-called "dissolved mucin"—Webster and Komarov, 1932; Komarov, 1935) is secreted partly by the "chief (or mucous) cells of the neck" and partly by the peptic cells. However, very little is known as to the conditions governing their activity under various physiological and especially under pathological circumstances. Of the clinicians MacLagan (1934) considers it possible that in the human gastric glands these cells secrete a fluid containing neutral chloride.

All the above theories regarding the variations in the acidity of the gastric juice are based almost exclusively on data obtained from the investigation of healthy animals. The variations in the composition of the gastric juice in such cases are not at all great and this makes it difficult for the advocates of one theory or another to offer convincing proof of the correctness of their surmises. Thus the gastric glands of the dog, even when stimulated to activity by such different agents as vagal impulses and histamine, produce a juice with an almost maximal content of hydrochloric acid. We (Babkin, 1931; Toby, 1936) have shown that under these circumstances the parietal cells are able to secrete almost all the chloride of the juice in the form of hydrochloric acid. But does this mean that the parietal cells are under all circumstances able to concentrate the chloride from the blood and to combine almost all of it with hydrogen-ions? It seems to me that the best approach to a solution of this problem—a problem which has occupied the attention of investigators for more than half a century—would be by careful study of clinical cases and by special experiments on animals in which certain pathological conditions of the gastric secretory function have been reproduced. It might be expected that under the influence of a pathological process some phases of glandular activity would become exaggerated, others diminished or even perverted, so that the entire functional capacity of a particular group of secretory cells would be revealed.

(2) In normal canine gastric juice, secreted under

either nervous (sham-feeding) or histamine stimulation, the greatest part of the fluid and of the total chloride is produced by the parietal cells. This is evident from the data obtained by Miss Toby (1936), who showed that the concentrations of total chloride in "sham-feeding" juice and "histamine" juice are practically equal and are maximal in both secretions. Whereas the "sham-feeding" juice is extremely rich in organic material (*e.g.* pepsin, mucin), the "histamine" gastric juice is almost completely devoid of it. If the organic material produced by the peptic and mucoid cells were secreted along with a considerable amount of fluid, the total chloride of the "sham-feeding" juice would have to be much lower than that of the "histamine" juice, because in the secretion from these cells the chloride concentration is presumably much less than in the parietal secretion. However, this is not the case. Therefore it may be assumed that under normal conditions the peptic and mucoid cells of the dog's gastric mucosa discharge their colloidal organic material with a minimal amount of fluid. This is in agreement with the well known fact (*cf.* Katsch, 1926, p. 447; Bloomfield and Pollard, 1933, p. 41) that in some cases of achylia gastrica in humans it is possible to obtain from the stomach a small amount of secretion, possessing peptic power but no acidity. In some dogs the neutral chloride of the "sham-feeding" juice may be slightly higher than that of the "histamine" juice (*e.g.* 52 and 32 mg. per cent respectively—Toby, 1936); at all events, in both these types of gastric juice it constitutes only a very small proportion of the total chloride secreted.

What is the composition of pure, human gastric juice? The nearest approach to normal gastric secretion is that obtained in response to histamine administration. This secretion is uncontaminated, and neither diluted nor partly neutralized by saliva and the food substances of a test-meal. But, as we shall see later on, it merely represents the result of the secretory activity of one particular group of glandular cells, namely, the parietal cells. Miss Toby (1937b), working in our laboratory and in co-operation with the Royal Victoria Hospital, Montreal, analyzed the "histamine" gastric juice of some normal persons and some patients. Only absolutely pure samples of the juice were employed. Human "histamine" gastric juice was found to differ from normal canine gastric juice in the following respects. There was no great difference in the two juices as regards acidity and total chloride concentration, although the values for both moieties—especially for the acidity—were lower in the human gastric juice. The most striking difference was in the content of neutral chloride. Whereas in dog's histamine juice it averaged only 32 to 41 mg. per cent, *i.e.* 5.6 to 7.2 per cent of the total chloride, in normal human gastric juice secreted in response to histamine it averaged from 103 to 132 mg. per cent, *i.e.* 19 to 26 per cent of the total chloride. The concentration of the organic constituents (total nitrogen, dissolved mucin and pepsin) was also much higher in the human gastric juice. The concentration of pepsin was particularly high; very often it was as much as 2,000 Mett units, equalling the highest values for pepsin found in canine juice elicited by stimulation of the vagi. We cannot yet adequately explain such an abundance of pepsin in the human gastric juice. At all events Miss

Toby's observations show what a powerful and at the same time potentially dangerous digestive agent man possesses in the gastric juice.

(3) It has been conclusively established in our laboratory (Babkin, 1930; Vineberg and Babkin, 1931; Webster, 1931; Bowie and Vineberg, 1935; Toby, 1936), and independently of us by Gilman and Cowgill (1931), that the parietal cells are practically the only cells of the gastric glands that are stimulated by histamine, this substance exerting hardly any excitatory effect on the peptic and mucoid cells. It is true that under a small dose of histamine (*e.g.* 0.5 mg. to a dog of 15 to 20 Kg. body-weight) the concentration of pepsin and other organic substances in the gastric juice does not fall to an extremely low level or become practically nil, but it is incomparably less than in the juice obtained by means of sham-feeding (Webster, 1931). In a very carefully controlled investigation on man Welin and Frisk (1936), using a double gastric and duodenal tube, compared gastric secretions obtained with insulin (20 units) and histamine (1 mg.) respectively. Whereas the concentration of total chloride in the "insulin" gastric juice (15 m.eq. per liter) was only a little less than in the "histamine" gastric juice, the total acidity in the former (100 m.eq.) was markedly less than in the latter (150 m.eq.). On the other hand, there was a fair amount of mucus in the juice throughout the insulin test and only traces of it after histamine. This is proof that in man also histamine acts selectively on the cells of the gastric glands. No pepsin determinations were made by Welin and Frisk. Thus, even if it be maintained that histamine is capable of stimulating the peptic cells, it must be recognized that its effect is very weak and variable. In fact, it has been demonstrated in our laboratory (Alley, 1935) that histamine inhibits the secretory activity of the peptic cells and possibly that of the mucoid cells (chief cells of the neck).

Having regard to what has been said above (§2), and as might be expected, histamine produces a copious flow of gastric juice having a maximal content of total chloride and acid and very low peptic power. The first samples of juice obtained after histamine administration usually possess a moderate digestive power (for coagulated egg-white), which, however, quickly diminishes and may disappear altogether in the subsequent samples. This was attributed to the "washing-out" effect resulting when a flow of parietal secretion carries off the colloidal secretion of the peptic cells accumulated in the glandular tubules during a period of rest or of diminished activity of the gastric glands. The inhibitory effect of histamine on the secretory activity of the peptic cells must also be taken into consideration.

The above-mentioned peculiar action of histamine on the gastric glands is daily observed in the laboratory in experiments on dogs and cats. However, many clinicians do not agree that histamine exerts a similar effect on man, believing that the administration of histamine in the human subject results not only in a flow of acid gastric juice but also in an increased output of pepsin (Pollard, 1932; Bloomfield and Pollard, 1933; Rivers *et al.* 1936; Osterberg *et al.* 1936—to quote only the more recent papers). Miss Toby (1937a) in our laboratory re-investigated this problem on some patients in the Royal Victoria Hospital. First of all it must be remembered that usually a much

larger dose of histamine is injected in animals than in human subjects. Whereas the former receive from 0.5 to 0.66 and even 0.75 mg. per 10 Kg. of body-weight, the latter are given as a rule not more than 0.1 mg. per 10 Kg. Therefore Miss Toby proceeded to test in one and the same patient the effects of a small dose of histamine (0.5 mg.) and of a larger dose (1.0 mg.). With the smaller dose, the result was indefinite as regards pepsin concentration, but with the larger dose it was quite striking. As soon as the volume of the secretion increased, the concentration of pepsin fell, and it remained at the same low level or even fell still further when the flow of juice diminished. This is to be explained by the fact that, after most of the pepsin previously accumulated had been "washed out" from the glandular tubules, there was not a sufficient secretion of pepsin to restore the concentration of this enzyme in the juice to its former level.

Another special feature observed by Miss Toby in all the patients investigated was the so-called "fasting secretion" of the gastric glands. When the secretion provoked by histamine was superimposed on this continuous "fasting secretion," the very variable enzymatic content of the latter was reflected in the composition of the gastric juice. Therefore in man the output of pepsin cannot be taken as a true indication of the effect of histamine on the peptic cells, even though this substance may be credited with exerting some stimulatory effect. In their last paper Rivers and Vanzant (1937) recognize the phenomenon of the "washing out" of pre-formed pepsin during secretion provoked by histamine. However, they still maintain that histamine actually elicits a secretion of pepsin (unfortunately through some error they ascribe this function to the parietal cells). They employed a double histamine test in human subjects, administering small doses of the drug. The second injection of histamine, given ten minutes after the gastric secretion provoked by the first dose had greatly diminished, produced a less marked, though still considerable rise in the concentration of pepsin in the juice. These authors argue that, in the short interval between the two injections of histamine, pepsin could not accumulate in sufficient quantity in the tubules. Nevertheless, there is the possibility that this was so. In their experiments the maximum secretion of pepsin occurred during the twenty minutes following the first histamine injection and probably coincided with the initial copious secretion of fluid. Most of the parietal cells are located in the neck of the glandular tubules and only a few are found in their lower part, which is occupied chiefly by the peptic cells. Therefore pepsin has time to accumulate in this part of the tubules during the period when the parietal cells are less active, which lasted in Rivers and Vanzant's experiments from 30 to 40 minutes. The second injection of histamine produced at the beginning of the secretory period a maximal effect (for the dose of histamine employed) on all the parietal cells, including those situated at the bottom of the gland. It is probably the profuse secretion from these cells that washes out pepsin accumulated in the lower part of the tubules.

Another argument against Rivers and Vanzant's explanation is the fact that both the concentration and the output of pepsin continuously fell almost to the very end of the experiment. Even if it is the case that histamine is able to stimulate the activity of the peptic

cells, its positive effect must be neutralized in some degree by the inhibitory effect of the drug on these cells—a fact which Rivers and Vanzant have not taken into consideration.

I realize that at the present stage of clinical research on these problems and in their application to medical practice these details of glandular activity may seem unnecessary to the physician. But of what value then is the determination of pepsin in the gastric juice if the drug employed for the production of the secretion is a specific stimulant for only one group of cells, i.e. those secreting hydrochloric acid solution, and has no definite relation to the activity of the peptic cells and may even inhibit their effect? I repeat here what I said in 1930, namely, that histamine is the best known test for the functioning of the parietal cells and may be used with great advantage for the purpose of determining the ability of the human gastric glands to secrete fluid and hydrochloric acid, but nothing else.

(4) Such is the state of affairs in perfectly normal animals and in healthy humans. Under pathological conditions the relations are much more complicated. It is a fact of common knowledge among clinicians that in certain pathological cases the acidity of the gastric juice may be considerably below normal, whereas the concentration of total chloride may remain approximately at a normal level (Katsch, 1926, p. 450). Might these changes in the composition of the gastric juice be due to an excessive secretion of alkaline gastric mucus? Opinions on this point differ. A well known German gastro-enterologist, Katsch (1926, pp. 446 and 450), states definitely that cases of true "*Hypochlorhydric*" sometimes occur. By "*Hypochlorhydric*" he means a pathological condition in which some secretion is still produced, but the HCl concentration is greatly diminished or this constituent may even be completely absent from the juice. Under these circumstances the gastric glands lose their ability to concentrate acid up to the normal level, although the secretion of total chloride is little affected. Katsch proposes to discriminate between cases of achylia gastrica with cases and, without "*Hypochloric*." In the latter not only is the acidity of the juice diminished but the total chloride concentration as well. Later on the gastric glands may also begin to lose the capacity to produce gastric juice with a normal content of chloride, and the volume of the secretion may also diminish. Of the American clinicians, Chron and Reiss (1921) have drawn attention to a special type of gastric hypersecretion which is not accompanied by hyperacidity and may even be found in cases of complete anacidity.

On the other hand Welin and Frisk (1936) hold the view that there is no alteration in the mode of hydrochloric acid secretion in cases of hypoacidity. The submaximal values for the acidity they attribute to the decreased rate of gastric secretion and the neutralizing and diluting effect of the mucus being continuously produced by the gastric mucosa.

The clinical literature on gastric secretion is enormous and very conflicting. The chief criticism that may be made against the results of so many of the earlier investigations on man is the unsatisfactory technique employed in obtaining pure gastric juice. It was not until the introduction of the histamine, and later of the insulin test that the clinician had the

opportunity of studying a more or less pure secretion, although in the case of histamine not all the different cells of the gastric glands are activated but only those responsible for the formation of hydrochloric acid. As an investigation of pathological cases seemed to be so essential to an understanding of the normal secretory processes of the stomach, Miss Toby (1937a) at my suggestion studied the composition of the histamine gastric juice of some patients with gastric or duodenal ulcers, applying the same chemical methods as she used in the investigation of canine gastric juice. In this study only samples of juice that were absolutely uncontaminated with food-residues, saliva or duodenal juices were subjected to chemical analysis. It was found that in the gastric ulcer patients the acidity of the juice and its concentration of total chloride were lower, while the neutral chloride was much higher than normal. Whereas in normal persons the chloride present as neutral chloride constitutes from 19 to 26 per cent of the total chloride of the juice, in this group of patients it averaged 50 per cent of the total chloride. The volume of juice secreted in response to the same dose of histamine was on the average less than in normal persons. In the duodenal ulcer patients the acidity of the gastric juice and its concentration of total chloride deviated very little from the normal. The percentage of chloride present as neutral chloride was from 17 to 31, i.e. it was practically the same as in the juice of normal subjects. There was a tendency to hypersecretion.

How are these facts concerning gastric ulcer to be interpreted? One explanation might be that the ability of the parietal cells (1) to convert neutral chloride into hydrochloric acid, and (2) to concentrate chloride up to the normal level, becomes impaired. This is indicated by the lower concentration of the total chloride, the lower acidity and the abnormally high concentration of neutral chloride in the juice.

Another interpretation that suggests itself is that the secretion of gastric juice (of constant acidity) is diminished and therefore the acid is more effectively neutralized and diluted by the gastric mucus than normally. Unfortunately this simple explanation is unacceptable owing to the following facts. In some of the gastric ulcer cases the concentration of total chloride in the juice was fairly high (up to 480-490 mg. per cent) and the total acidity rather low (219-257 mg. per cent), although the volume of mucus was less than in normal subjects. In some other cases, where the rate of secretion was almost normal, the total chloride concentration (e.g. 320 mg. per cent) and the total acidity (e.g. 141 mg. per cent) were too low to be explained by a slight increase in the total secretion of mucus.

Yet another explanation of the peculiarities of the gastric juice in gastric ulcer patients might be offered, viz. that under pathological conditions the secretory activity of the various cellular groups lining the gastric tubules is altered quantitatively. The parietal cells then produce a less amount of acid secretion, as shown by the diminished volume of the gastric juice. On the other hand, the secretion of other cell groups—namely, the peptic cells, chief cells of the neck and surface epithelium mucous cells—may be increased. Therefore the secretion of neutral or slightly alkaline

fluid with a low concentration of chloride will be more abundant than under normal conditions. As a result, the gastric juice will be less acid, although the parietal cells will continue to secrete a fluid of constant acidity, and it will contain less total chloride and more neutral chloride. It is difficult to say which of these cellular groups is in a state of hypersecretory activity in a patient with gastric ulcer. The quantity of visible mucus produced by the surface epithelium varied greatly from patient to patient and in several cases was even lower than normal. Therefore this mucus can hardly be held responsible for the changes in the composition of the gastric juice of the gastric ulcer patients investigated by Miss Toby. Neither did the peptic cells display exaggerated activity in gastric ulcer patients, for the peptic power of the juice was *not at all high*. This was only to be expected, since the secretion of gastric juice was provoked by histamine. Furthermore, the peptic power varied greatly from case to case. It had no relation to the concentration of neutral chloride. Thus the "chief cells of the neck" remain the only group of secretory elements which may be held responsible for the dilution and neutralization of the acid parietal secretion. Unfortunately we have no direct proof that such is the state of affairs, but if this supposition is really correct then it is clear (1) that the chief (or mucous) cells of the neck are somehow affected by the ulceration process, and (2) that they respond to histamine stimulation to a far greater extent than under normal conditions.

I must frankly admit that none of these explanations satisfactorily answers the question under discussion. Whereas normally the activity of the different cellular groups in the gastric glands is strictly confined to one definite function or another and the activity of each group is finely adjusted to that of the others, in the diseased gastric mucosa these relations may be distorted. Under normal conditions the parietal cells produce a fluid secretion of practically constant acidity, and the peptic cells and mucous cells of the neck discharge their secretion with a minimal amount of fluid. In pathological cases several possibilities of deviation from the normal functioning may be assumed. Thus the activity of one group of cells may be increased over that of another; or a particular group of cells may lose its capacity to function with the same precision as normally; or another group of cells becomes overexcitable and now responds with exaggerated secretion to stimuli which under normal conditions hardly affect it at all. The physiologist seldom has the opportunity of observing these and other deviations from the normal. They may be studied perhaps by means of specially planned experiments in which the function of different groups of gastric cells is revealed. However this may be, before we accept any theory of gastric secretion which can be applied equally satisfactorily to the interpretation of normally and pathologically functioning gastric mucosa, a great many more experimental pathological, as well as carefully controlled clinical studies must be performed. I firmly believe that a full understanding of the secretory mechanism of the gastric glands can be finally achieved only through the closest co-operation between laboratory and clinic.

Report of an Apparent Case of Secondary Pellagra*

By

M. B. HOLOMAN, M.D.

and

HOMER I. SILVERS, M.D., F.A.C.S.

ATLANTIC CITY, NEW JERSEY

IT is rather surprising that after a considerable search no clear nor accurate description could be found dealing with the state of the rectum and colon during or after an attack of Pellagra.

Diarrhea is a common symptom in Pellagra and being common has apparently been accepted as diarrhea without further investigation. We find no detailed records of proctoscopic examination with descriptions as to what the mucosa may look like nor as to the structural state of the rectum and lower colon.

It would at least be interesting to know the results obtained from a series of post mortem studies upon the changes that take place in Pellagra. There may be such a study but the common disposition in the current literature is to speak of a diarrhea that has symptoms of variable degrees, sometimes preceding the other symptoms, and at other times present in severe form towards the end of the disease. That diarrhea occurs in Pellagra is evident, but it is not so clear just what destructive processes accompany this disease.

It has been shown that Pellagra occurs with, or secondary to, various chronic lesions of the intestinal canal, particularly those lesions that are destructive to the mucosa or those that interfere with the functions of this membrane.

Ian Murray (1), writing in the Glasgow Medical Journal, quotes Fakhry as finding that "a definite relationship between the incidence of Pellagra and intestinal schistosomiasis, and also recalled the fact that among sixty-five German prisoners of war who developed Pellagra, sixty-three were suffering from amoebic dysentery or bacillary dysentery.

Turner (2), in the American Journal of Tropical Medicine, makes the observation that "most of the exhaustive monographs in Pellagra give little information concerning organic lesion of the gastro-intestinal tract in this disorder. Most of them refer to chronic gastritis and ulcers in the large and small intestines." His work in the Charity Hospital has led him to the conclusion that gross organic disease of the gastro-intestinal tract may be associated with Pellagra much

more commonly than is generally detected. He reports 16 cases out of 75 seen as having definite gastro-enterological changes, most of which occurred in the lower or terminal gut.

Larimore (3) discusses a case in which for ten years there was persistent ill health marked by duodenal ulcers for which a number of operations were performed, including gastro-enterostomy, two explorations for hepatic abscess and re-operation for gastric and duodenal drainage. In this patient Pellagra developed.

Eusterman and O'Leary (4) discuss the probable secondary invasion by Pellagra and report 13 additional cases.

Numerous reports through the literature have led to the conclusion that Pellagra apparently does appear as a secondary manifestation in a proportion of individuals ill from various diseases of the gastro-intestinal tract.

The following report is that of a young colored male whose predominating symptoms were rectal and lower colon inflammation, that this inflammation was present for a long time preceding the pellagric symptoms, and that extensive changes took place in the rectum and sigmoid with marked deformity occurring.

HISTORY

A patient, J. J., Negro, male, age 23, admitted to the Atlantic City Hospital, April 23, 1935, with the chief complaint of diarrhea and pain in the rectum. The family history and past personal history were essentially negative. The history of the present illness revealed that a bloody diarrhea occurred about three years prior to the present time, at which time he had eight to nine bowel movements a day, lasting about four days; treatment not ascertained. Two years later, December 1, 1934, or five months prior to admission to the Hospital, there re-occurred the loose bowel movements having from nine to twelve a day with bleeding and griping pains in the abdomen, which condition persisted for approximately two months; during which time he had lost thirty-five to forty pounds. There was no loss of appetite at any time. For the next three months, the patient had only about five to six pass-

*From the Proctologic Service, Atlantic City Hospital.

ages per day. During these five months there was a progressive weakness and an occasional numbness of extremities.

PHYSICAL EXAMINATION

Revealed a very emaciated, young adult Negro male, with general physical findings essentially negative. The recto-sigmoidal examination revealed a marked wasting of the ischio-rectal space, external skin tags present, slight eversion of the mucous membrane and a complete loss of external sphincteric tone. A digital examination further disclosed no pathology. Upon passage of the sigmoidoscope evident ulcerations were noted beginning at the ano-rectal junction and extending well into the rectosigmoidal region. The ulcerations were deep, bled easily and profusely and were of no particular type or size with irregular spacing. There were areas of more or less normal mucous membrane between areas of ulceration.

Initial laboratory findings revealed a definite anemia, approximately three million R.B.C. with a 40% Hemoglobin, White Count showed no leucocytosis with a slightly abnormal increase of lymphocytes. Only slight kidney pathology was noted in the urinary examination. The blood Wassermann and Kline were both negative. The Frei test was negative.

Study from every standpoint was made from time of admission. However, the diagnosis of Pellagra was not arrived at until after a month, when the dermatologic manifestations made it evident.

Subsequent proctologic examination revealed a fairly rapid rectal involvement which was at all times the predominating feature of the case with the bowel movements ranging from four to seventeen per day. The ulcerations became more numerous and more closely set until a gradual coalescence occurred bringing about a gradual destruction of the bowel structure. Beginning about the eighth month there was notice of some stenosis with the formation of small adenomata which were rather numerous. Finally during the last month of life, the bowel became contracted into a small tubular canal; beginning about one inch above the ano-rectal line, it was hard, firm and more or less rigid, so that the proctoscope could not be passed. The area that could be seen was one mass of ulcerations without any areas of normal mucous membrane. When near the last a definite obstructive element came into play, an ileostomy was resorted to; finding in this

region at operation a bowel relatively free of involvement, which bore out X-ray findings, pre-operatively. This operation was resorted to mainly in an attempt to give the patient comfort. However, death occurred five days later.

Throughout hospitalization, during a twelve month period, numerous smears were taken directly from ulceration and many more stool examinations were made in an attempt to isolate Amoeba, B. Shiga, and B. Flexnor, diplostreptococci and other organisms with repeated negative findings; there being reported only those organisms normally inhabiting the gastro-intestinal tract. There was used empirically specific treatment for Amoebiasis. Bargain's vaccine was used as was all means of dietetic regimes and vitamin therapy, to no avail. The greatest amount of improvement, and that very slight, was believed discerned with the use of Calcium therapy with parathyroid extract. The blood picture was essentially unaltered by numerous transfusions and various other means. The range in weight was from ninety to one hundred pounds.

In this individual the predominating symptoms were those of an intense colitis and these symptoms were justified when examination by proctoscope was made.

The gross change in the bowel was perfectly obvious as well as extensive, producing in the ampulla of the rectum such changes in shape, size, and contours, that the finger could not be passed and eventually produced obstruction.

This violent inflammation had been going on for months before there was any change in mental state, nervous phenomena or skin manifestations. These changes in mental state, and dermatologic findings came so late in the disease that we were led to believe that the Pellagria state could have been secondary to the ulcerative colitis.

A Case of Peptic Ulcer in a Child Following Brain Injury

By

FRANCES R. VANZANT, M.D.

and

JAMES A. BROWN, M.D.

A POSSIBLE relation between intracranial lesions and the presence of gastro-intestinal ulceration had been suggested repeatedly but not until 1932, when Cushing published his review of this subject, was this a commonly recognized and accepted observation.

Cushing reported three cases of acute perforating

gastro-intestinal lesions which followed operations for cerebellar tumor. He also cited two cases of gastric erosions following operations for brain tumor, two cases of gastric ulcer associated with malignant hypertension with choked discs, the case of a child of ten with a chronic cicatrizing duodenal ulcer associated with a recurring cerebellar tumor, and the case of a

man with duodenal ulcer who had recurrence of gastric distress associated with each of three exacerbations of intracranial symptoms from a radio-sensitive tumor encroaching on the third ventricle.

In verification of his observations the experimental production of gastric and duodenal lesions following various intracranial procedures has since been accomplished by Keller and his associates, who found that lesions in the neighborhood of the third ventricle were prone to produce changes in the gastro-intestinal mucosa, either hyperemia, erosion, or crater formation.

Although these observations are significant because of their bearing on theories of the etiology of ulcer their importance is lessened because of the rareness of reported cases in which there is an unmistakable connection between the intracranial and the gastro-intestinal lesions. The actual incidence of such cases may be greater, however, than appear at this time. For this reason the following case is worthy of being placed on record:

The patient was a boy of eleven years, somewhat below average stature, but well nourished, vigorous and healthy. According to his mother's story, the only illness he had ever had occurred at long intervals, and consisted of "biliary spells" by which she meant spells of nausea, vomiting and constipation, accompanied by slight fever. After a dose of castor oil he always recovered promptly.

On October 22, 1936, he was struck by a truck and knocked unconscious. He regained consciousness after a few minutes and was later taken to the hospital where he was treated for concussion and an injured right foot. During the first twenty-four hours after the injury, he vomited repeatedly, but improved rapidly thereafter, and was allowed to go home on the fourth day and to return to school in another ten days.

Twenty days after the accident he began to complain of a dull aching in his frontal region particularly above the left eye, occurring usually in the morning hours shortly after arising. There was some vertigo and occasional diplopia. His eyes burned and hurt him if he read. His appetite began to fail at this time and he complained of sharp, severe pains in the epigastrium a little to the left of the mid-line. The pains occasionally occurred as he was eating, lasted for a few minutes and then subsided.

Six weeks after the injury he was first seen by Dr. Brown, who made a diagnosis of contusion and laceration of the brain with sequelae of headache and disturbance of vision. The extent and location of the brain lesion could not be determined in the absence of localizing signs. He was extremely nervous. Lumbar puncture showed an increased cerebro-spinal fluid pressure of 180 m. m. of water. The treatment prescribed consisted of a low fluid—low salt diet, rest, and one and one-half grains phenobarbital daily.

Dr. T. J. Vanzant investigated the visual disturbance and found a marked convergence insufficiency with a near point of convergence at 600 m. m. Orthoptic training was instituted.

Because the differential blood count revealed a ten per cent eosinophilia, examination of the stools were made with the result that it was discovered that they contained a large amount of blood. The boy had not noted that his stools were tarry but the mother recalled that on December 18 and again two days later the boy had suddenly grown quite pale and felt weak.

Fluoroscopic examination of the stomach and duodenum was then requested and showed a normal stomach, but the duodenum was small, irritable, and showed a constant deformity. A diagnosis of superficial duodenal ulcer was made.

He was then placed on a diet consisting of six feedings of bland food, restricted as to liquid and to salt content. He was given six doses of an aluminum silicate preparation each day. The dosage of phenobarbital was increased to two and one-fourth grains daily. On this management headache disappeared, nervousness was controlled, and abdominal pain ceased. There was no recurrence of gross bleeding, and repeated stool examinations disclosed no occult blood.

After one month the diet was made more liberal but the salt and water content was kept low and coarse foods were prohibited for two months more at which time he had apparently recovered from all evidence of intracranial and gastro-intestinal disturbances. The eye condition returned to normal under orthoptic training, the near point of convergence decreasing from 600 m. m. to 40 m. m.

Since the history prior to the accident had never suggested the presence of a duodenal ulcer, which is, of course, extremely rarely diagnosed in children of this age, and since the ulcer seemed to be an acute, shallow, recent one from the X-ray appearance, we conclude that it arose during convalescence from the brain trauma. It is to be recalled that there was recurring vomiting for the first twenty-four hours after injury, after which his condition rapidly improved. It was not until post-concussion symptoms appeared that epigastric pain and melena occurred.

Since the patient was suing for compensation the question of prognosis was important. Would the well known tendency for ulcer to recur be manifest in this boy later in life? If the injury to the brain was the precipitating factor in the development of the ulcer, we would not expect recurrence of trouble in the duodenum unless there should be recurrence of neurological symptoms also.

Unusual Hematemesis or Gastrorrhagia

Hereditary Hemorrhagic Telangiectatic Dysplasia with Gastrostaxis or Stomachorrhagia (Goldstein's Hematemesis)

By

HYMAN I. GOLDSTEIN, M.D.
CAMDEN, NEW JERSEY

GASTRIC hemorrhage is frequently looked upon as a catastrophic and serious complication. Rarely one meets with massive hematemesis that does not require emergency or operative interference. The occurrence recently of two cases with recurrent massive gastrorrhagia due to gastric telangiectatic dysplasia in the same family lead me to make these few remarks.

In such cases, injections of Moccasin snake venom (Lederle's, N. Y.), as used by Peck & Rosenthal, of Mt. Sinai Hospital (New York)—[Arch. Dermat. and Syphil., 35:831-864, May, 1937] may be effective in checking and preventing such telangiectatic bleeding. Russell viper venom ('Stypven,' B. & W., London), in solution, given orally, has checked gastric bleeding.

In addition to these measures, one may use (intravenously) Congo red solution and calcium gluconate, with or without intramuscular injections of parathormone, where blood transfusions are not possible or have failed to control the bleeding. Concentrated liver extract injections and cebione or (ascorbic acid and vitamin "P") may also be helpful.

Gastric bleeding, when not due to ulceration, neoplasm, polyposis, portal thrombosis, gastric allergy, hepatic cirrhosis, varices, blood dyscrasias, Geisböck's disease, "haematemesis puellaris," arterial nevus or varix of the lower end of the esophagus, angioneurotic edema, thrombophlebitic spleen, erythema multiforme with gastro-intestinal manifestations (Osler), splenic anemia (Banti's disease or "Klemperer's anemia"), other severe anemias, leukemias, Hodgkin's disease, scurvy, gastritis, and uremic states, may sometimes be explained by the presence (noted gastroscopically) of gastric telangiectases in patients suffering from *Rendu-Osler-Weber's disease* or *Goldstein's Hereditary familial Angiomatosis* with recurring hemorrhages.

Of interest in this connection are the reports by John Abercrombie (1780-1844)—[IV. "Haemetemesis" in "Pathological and Practical Researches on Diseases of the Stomach, The Intestinal Canal, The Liver, and Other Viscera of the Abdomen"—pp. 80-81, 1828, (London and Glasgow), Edinburgh, Waugh and Innes]; Sir George Burrows ["Constitutional hæmatemesis, particularly in females"! Tweedie's Library of Medicine, Vol. 5, p. 38, 1840]; T. H. Sawtell [Clinical Society's Transactions, London, 19:1-4, 1886]; W. Hale White ["Gastrostaxis" or "Hæmatemesis without ulceration," Lancet, Vol. I, No. 4061, 1819-1820 (June 29), 1901; No. 4340, II, 1189-1195 (Nov. 3), 1906; Vol. I, p. 416, 1912]; Donald W. C. Hood ["Hæmatemesis, with special reference to that form met with in early adult female life"—Trans. Med. Society of London, 15:283-297, 1892]; James Hamilton ["Observations on the Utility and Administration of Purgative Medicine in Several Diseases"

—6th Chapter: pp. 108-117, 1805, Edinburgh, C. Stewart]—speaks of "one variety of hæmatemesis which attacks females who are from eighteen to thirty years of age; and it rarely appears sooner"—(Vicarious menstruation), and J. Lordat (1773-1870) of Montpellier—[Traite Des Hemorrhagies, p. 6 and p. 86, 1808, Goujon, Brunot-Labbe, Paris; "First Lines of the Practice of Physic," Book IV, Chap. I, Sec. II, Para. 744, etc.—In Chapitre IV, ("Hemorrhagies par fluxion locale"; 3e Genre.), p. 86, Lordat refers to the report by Helwich (Morb. Uratislav., 1701)].

Ashwell ["Chlorosis and its Complications"—Guy's Hosp. Reports, Vol. I, 1836] regarded chlorosis as connected with amenorrhea and stated "a vicarious discharge of blood from the stomach by vomiting is not an unusual concomitant of protracted chlorosis and amenorrhoea." W. Leube alludes, also, to such possible association [Ziemssen's Cyclopaedia of the Practice of Medicine, Vol. VII, 271 and 274, English Transl., 1876, Wm. Wood & Co., New York; "Hemorrhage of the Stomach," pp. 269-293].

Sir George Burrows (1840) speaks of hematemesis independent of any apparent change of structure in the mucous membrane of the stomach or in any organ capable of influencing the circulation through that membrane "is certainly rare," although he believes he has met with several such cases. "Such cases usually occur in women between 30 and 40 years of age."

Reference should here be made to the publications by Dalche ["Essai sur L'Émbaras Gastrique Et Le Vomissement De Sang"—An. XI, 1803, Paris Thèses—Vide pp. 29-66—"Hématemese Ou vomissement de Sang"] who gives a historical review referring to early observations by C. Pinel, Henricus ab Heer, Riverius, Hippocrates, Hoffmann, Joh. Rhodius, Bartholinus, Lieutaud, de Lorry, Juncker, C. Portal, Morgagni, etc.; Latour (1828); W. P. Herringham [St. Bartholomew's Hosp. Reports, XLIV, 11-21, 1909]; A. G. Gullen (1906); B. Dawson (1905); Osler (1902), and Helwich (1701).

Helwich spoke of a woman who was 40 years old and had borne several children. Every year, in the Spring, at the end of the Summer, and in the Autumn, she brought up a quantity of blood from the stomach for a period of four days.

D. Latour (1828) says that Portal, Franck, Hoffmann, VanSwieten, Baldinger, Warton, and others have observed that among those who have died from gastro-intestinal hemorrhage, the mucous membrane of the stomach and intestine may not show any lesion from which the blood came! [Histoire Philosophique et Médicale des Hémorrhagies, Vol. I, 287, 1828, Paris].

Dalche (1803) says that gastric bleeding without lesions are commoner in virgins and that the hemor-

rhage most usually occurs in the Spring and Autumn, and mentions further, that after death there may be no erosion of the internal surface of the stomach.

Ashwell ["Observations and its Complications"—with cases—Guy's Hosp. Reports, Vol. I, 529-579, 1836] reports Cases 5, 6, 7, 8 and 9, which are of particular interest in connection with the above remarks. In Case 5, he reports a delicate girl of 16 years, suffering from "chlorosis complicated with vicarious discharge of blood and disorder of the stomach and bowels"—(pp. 561-562). She had severe attacks of hematemesis and occasional epistaxis, and two lighter attacks of gastric hemorrhage.

Richard M. Smith and Sidney Farber, of Boston, discuss splenomegaly in children with early hematemesis (Jour. of Pediatrics, 7, No. 5, 585-608, Nov., 1935).

Bertrand Dawson [Brit. M. J. II:1032, 1905] believes hematemesis in young women to be due to the menstrual molimen, if not to vicarious menstruation, and used the term "*hæmorrhagic gastralgia*," while Donald W. C. Hood's term (1892) is "*hæmatemesis puerilis*."

The case of fatal hematemesis, reported by Carnot, Rachet and Delafontaine [Bull. et mém. Soc. Méd. d. hôp. de Paris, 53:538-541 (May 13), 1929] was due to hemorrhage from an arterial nevus of the esophagus.

W. P. Herringham ["On Gastric Ulcer and Gastrostaxis." St. Bartholomew's Hosp. Reports, 44:11-21, 1909] commends (p. 12) on a form of hematemesis in young women akin to the epistaxis common among boys, and which might be called, by Hale White's term, "*Gastro-staxis*" (1906) or dripping of blood from the stomach. He showed a case of gastric bleeding not dependent upon ulcer.

Sir Thomas Watson, in his Lectures [Vol. II, p. 496, 1871, 5th Ed.] also mentions hematemesis occurring as vicarious menstruation.

W. Hale White collected 29 cases of gastrostaxis [Lancet, No. 4340, 1189-1195 (Nov. 3), 1906] and states "are not some patients said to be afflicted with gastric ulcer really suffering from a different disease?" He says further, frequently in women, between 20 and 40 years, associated with chlorosis, and at times occurring apart from chlorosis, hæmatemesis is met with, without any ulceration.

Gastric capillary hemorrhages are not uncommon as the result of increased permeability of the mucous membrane caused by allergic reactions. Sante (1936) reported massive hemorrhage from the gastro-intestinal tract attributed to allergy. Gastrorrhagia, due to allergic reactions, have also been reported by Andresen (1934); R. A. Gutmann (1932); Crispin (1915 and 1916); Morris (1904); Halstead (1905); Osler (1904 and 1914); A. Tzanck (1932); Dutton and Lintz (1925); Albert Rowe (1937), and others have mentioned gastro-intestinal bleeding due to food allergy.

We might recall Vidal's "*COLLOIDCLASSIC DIATHESIS*," and Bray's "*ALLERGIC DIATHESIS*" or the inheritance of the tendency to develop allergic reactions—the transmission of allergic propensities, (such as are rarely, if ever, observed in animals).

Rowe (1937) states: "an exaggerated tendency to allergy is not only transmitted, but that the tendency to develop certain types of allergy such as pollen, animal emanation, or food allergies often is inherited." [Rowe: Clinical Allergy, p. 45, 1937, Lea & Febiger, Philadelphia].

Gastro-intestinal allergy occurs not infrequently in patients suffering with bronchial asthma, especially when due to food sensitization.

Enfield [Amer. J. Digestive Dis. and Nutrition, 3, No. 1, 69-70, March, 1936] reported on "Gastro-Duodenal Hemorrhage of Unknown Origin."

Osler spoke of "Hereditary angioneurotic edema"—[Am. J. Med. Scs., 95:362, 1888] and discussed "The Visceral Lesions of Purpura and Allied Conditions" [Brit. Med. J., I:517, 1914]. An important contribution by Osler was his paper "On the Surgical Importance of the Visceral Crises on the Erythema Group of Skin Diseases"—[Am. J. Med. Scs., 127:751, 1904].

Mention of interesting instances of gastric bleeding, not due to any organic lesions in the stomach, was made by Stephen Mackenzie; Habershon; Sidney Phillips (1887); Jacques Lordat (1808); Andral (1828); Chomel, and Prof. W. Leube, of Jena.

Norah Schuster's (Jan., 1937) case of "*familial telangiectasia*" showed numerous gastric and duodenal telangiectases with multiple aneurysms of the splenic artery at necropsy [Jour. Path. and Bact., 44, No. 1, 29-39, Jan., 1937].

Probable cases of gastrostaxis and telangiectatic dysplasia of the stomach with gastrorrhagia (or "Goldstein's hematemesis") were those reported by Ullman, of Vienna (1896, 1900); W. H. White, of London (1906, 1912); Pons, Meine and Blunkle, of Asbury Park (1929); L. N. Boston, of Phila. [Am. J. M. Scs., 180:798, Dec., 1930]; White [The Lancet, I, No. 4061, 1819-1820, (June 29), 1901]; Guttmann, Laval and Schlumberger (1932); Benhamou (1933); Kessel [J. A. M. A., 97:1058 (Oct. 10), 1931]; H. I. Goldstein [Brit. Med. J., No. 3937, 1275 (June 20), 1936; Arch. Internal Med., 48, Part I, 836-865, Nov., 1931; Acta Dermato-Venerologica (Stockholm) XIII: Facs. 6, 661-694, Dec., 1932; Arch. Dermat. and Syphilol., 26:282-308, Aug., 1932]; "Goldstein's Hematemesis," J. A. M. A., 108, No. 14, 1202 (April 3), 1937]; Thomas FitzHugh, Jr., of Phila. [Am. J. M. Scs., 166:884, Dec., 1923; 181:261, Feb., 1931]; Matthew S. Ersner, of Phila., in his discussion of Goldstein's paper before the Medical Society of New Jersey, June 13, 1930, mentioned two cases of gastric bleeding of telangiectatic origin. The father of one of the patients mentioned by Ersner, suffered from stomachorrhagia, which led to an exploratory laparotomy, but apparently nothing was found at operation, and there was no abatement of the gastric bleeding! Other members of this man's family suffered from severe recurring attacks of nosebleed and numerous telangiectases ["Hereditary Epistaxis; with and without Hereditary (Familial) multiple Hemorrhagic Telangiectasia"—Jour. of the Med. Society of N. J., 28, No. 4, 309-327, April, 1931, Ersner's Discussion, pp. 326-327].

The Action of Histidine on the Gastro-Intestinal Tract*

By

LOUIS S. GOODMAN, M.D.

and

PHILIP A. BEARG, M.D.

NEW HAVEN, CONNECTICUT

HISTIDINE has recently been proposed and used for the parenteral therapy of peptic ulcer. The experimental work of Weiss and Aron (17, 18, 19) in five Exalto-Mann-Williamson dogs (E.M.W. dogs; transplantation of pancreatic and biliary portion of the duodenum into the terminal ileum, with continuity of the gut restored by anastomosis of pylorus and jejunum) has formed the meager background for the clinical use of this amino acid. Histidine apparently prevented gastrojejunal ulcers regularly occurring in these preparations. It was suggested that the inability of these dogs adequately to digest proteins resulted in a deficiency of essential amino acids, and that one of these, histidine, was necessary for the maintenance of the integrity of the gastro-intestinal epithelium.

The small number of animals and brief period of observation used by the above authors, however, rendered their work open to criticism. The recent report of Fauley and Ivy (2) on a large series of E.M.W. dogs shows that ulcers can be prevented by a special diet or fundusectomy. The conclusion that gastric acidity is more important than nutrition in the etiology of these ulcers is also supported by the experiments of Morton (10) who showed that such ulcers in dogs with surgical duodenal drainage into the ileum will heal if the stomach is again anastomosed to the jejunum at a point distal to the original ulcer. Barry and Florey (1) using the Matthews and Dragstedt operation on cats and young pigs (small fundic pouch anastomosed to the terminal ileum) were unable to demonstrate any prophylactic effect of histidine on the resulting ulcers. Stalker, Bollman and Mann (14) have shown that histidine will not prevent the formation of cinchophen ulcers in dogs, and Windwer and Matzner (20) were unable to prevent ulcer formation in rats (pepsin-HCl method) by using histidine. Indeed, they found that normal rats developed ulcers if injected with the amino acid.

The only report that might be considered as partially confirmatory of the original work of Weiss and Aron is that of Flood and Mullins (3). Of twelve histidine treated E.M.W. dogs, 45 per cent were apparently protected from ulcer formation, whereas all five control dogs developed ulcers. Elaborate chemical and pathological examinations, however, failed to show any difference between the control and histidine dogs to which the results might be attributed. Very recently, Sandweiss, Salzstein and Glazer (11) reported that in fourteen histidine treated E.M.W. dogs, 13 or 93 per cent showed ulcer formation; twelve controls all developed ulcers. They suggested that the results of Flood and Mullins may be due to the fact that the

latter workers divided the duodenum slightly below the pylorus, and that the duodenal stump remaining attached to the stomach possibly prevented the occurrence of ulcers.

Early clinical reports on the therapeutic efficacy of histidine injections in peptic ulcer patients were uniformly enthusiastic; but a careful scrutiny of these publications reveals few control studies, a lack of rigid selection of patients and criteria of cure, and no analyses of late results. Volini and McLaughlin (15) claimed that histidine reduced both the volume and acidity of gastric secretion of patients in response to test meals and histamine, and Gardiner (5) apparently confirmed this finding. All other workers have been unable to substantiate these results. In a later report, Volini and McLaughlin (16) suggested that histidine may act by virtue of stimulating a histaminase, which, in turn, inactivates histamine; thereby gastrin (gastric "secretin") is inhibited, thus reducing gastric acidity, secretion, and motility.

More complete and critical studies on large and adequately controlled groups of peptic ulcer patients have recently appeared, especially those by Sandweiss (12, 13), Martin (9) and Flood and Mullins (4). The conclusions were reached that the effects of histidine injections are mainly symptomatic and transient; that the extravagant claims made for this amino acid are unwarranted; that although parenteral therapy may be of some value in the small percentage of cases failing to respond to diet-alkali management, saline or distilled water injections produce as prompt and dramatic relief as does histidine. The possibility looms large, therefore, that the therapeutic effect of histidine is a psychic one.

When the experiments to be communicated in this paper were first undertaken (September, 1935), it seemed desirable to test in the laboratory effects of histidine on gastric function. Many clinicians were using histidine in an uncritical manner, and controlled laboratory studies of the possible gastro-intestinal actions of histidine were quite meager. The purpose of the study was to determine if histidine injections in any way altered the secretory response of gastric pouch and gastrotomized dogs previously standardized either to a histamine stimulus or test meals. In addition, *in vitro* tests were made of histidine effects on the tone and motility of rabbit intestine.

METHODS AND PROCEDURE

Animal Experiments: Five healthy adult female dogs were used. Three gastric pouch animals were prepared in the usual manner; in two, the accessory stomachs were innervated, the third was an Heidenhain preparation. Erosion of tissue about the pouch openings was prevented by a simple self-retaining rubber catheter technic devised by the authors (6), and alkali dressings were in this way

Submitted July 30, 1937.

FIG. 1. Gastric secretory response to histamine before and after histidine. Pavlov gastric pouch dog E. Weight, 16 kg. Each curve constructed from average values of at least ten trials. There is no appreciable change in either volume or acid values following a course of histidine.

completely eliminated. Two dogs were gastrotomized, and similar catheters with removable glass stoppers to prevent spillage of gastric contents were kept permanently in place. The pouch dogs were trained to the usual harness collection apparatus, and the routine precautions regarding Pavlov gastric pouch animals were carefully observed.

Standardization and testing were done as follows: One Pavlov pouch dog (E) weighing 16 kg. was standardized during ten trials for its fasting gastric response to histamine base, 0.1 mgm. per kg., administered subcutaneously as the acid phosphate salt. Samples were taken at fifteen minute intervals until resting values returned. Histidine* was then given intramuscularly once daily for thirty injections in the dose of 0.2 gm. (5 c.c. of a 0.4% solution of the monohydrochloride). During and after the course of histidine, dog E was again tested at intervals with histamine. At the conclusion of the histidine injections the responses to test meals of 450 grams of lean hamburger were also determined in this animal, and compared with known preinjection values for such test meals.

The two other pouch dogs were standardized to test meals over a period of eight weeks. Dog T, weighing 15 kg., with an innervated accessory stomach, received 300 grams lean hamburger, and dog J, weighing 20 kg., and with extrinsic nerves to the pouch severed, received 450 grams of a commercial dog food, Red Heart A, consisting of cereal, beef, soy bean flour, yeast, and cod liver oil. Hourly collections of pouch secretion were made until fasting levels returned, the volumes recorded, and acid values titrated. After adequate standardization, daily intramuscular histidine injections were given in the dose and number stated above with the exception that dog T received additional injections twice daily for ten days following the routine thirty doses. Experimental runs were made thrice weekly during standardization, twice weekly during the course of histidine injections, and once or twice weekly thereafter for from five to ten months. Pouch dog T, because of a very large accessory stomach secreting as much as 150 c.c. per hour at the height of response to the test meal, required the daily oral administration of supplementary sodium chloride in capsules in order to maintain a normal electrolyte balance.

The two gastrotomized dogs, A weighing 14 kg., and R, weighing 12 kg., were standardized to test meals of 300 and 200 grams of lean hamburger respectively, over a

period of two months. Thirty daily injections of histidine in the dose stated were then given, during and after which the gastric responses to the test meals were examined twice weekly. Samplings of gastric contents were made through the catheter at intervals until the stomach was empty. The samples removed were approximately 4 c.c. in volume. Such collections were immediately heated to boiling to arrest peptic digestion, centrifuged, the per cent of solid content recorded, and the supernatant juice analyzed as described below.

All specimens of pouch juice or gastric contents were titrated in one c.c. portions against N/50 NaOH delivered from a microburette. Töpfer's and phenolphthalein indicators were used to determine the free and total acid values respectively. Results were recorded in milliequivalents of acid per liter of gastric secretion or contents.

Gastro-intestinal fluoroscopic examinations* were made in pouch dogs E and J to determine emptying time and motility. Direct examinations of the mucosa of the accessory stomachs were made periodically with the aid of a cystoscope passed through the pouch opening.

In Vitro Experiments: Isolated strips of rabbit ileum were studied in an organ bath to determine the effects of histidine on intestinal tone and motility. Dilutions ranging from 1:500 to 1:2,000,000 were tested. Oxygenated Ringer-Locke solution at 37.5° C. was used as the bath fluid, and graphic recording of the smooth muscle contractions was made by means of the usual muscle lever-kymographic apparatus.

RESULTS

All the dogs remained in good health and maintained or increased their weights during the period of observation. No untoward local or systemic reactions to the histidine injections were seen. Direct examination of the pouches revealed normal gastric mucosa in all instances throughout the experiments.

I. Secretory response to histamine.

In Fig. 1 are shown the acid and volume responses to histamine obtained in gastric pouch dog E. This animal had a small pouch which secreted an average of around 4 c.c. in the fifteen minute period of maxi-

The pre-histidine curve represents the average of 25 experiments; the post-histidine curve, 45 trials over a period of ten months. Note the prolongation of the secretory period.

*The histidine used was Larostidin, kindly furnished by Hoffmann-LaRoche, Inc.

Fig. 3. Gastric secretory response to test meal before and after a course of histidine. Pavlov gastric pouch dog T. Weight, 15 kg. Fed 300 grams lean hamburger. Pre-histidine curve represents the average values for 20 standardization experiments; the post-histidine curve, the average of 18 trials. There is no significant alteration due to the injections.

mal response to histamine. Each value in the curves represents the average of at least ten determinations. It is at once evident that no appreciable difference occurred in either the volume or acidity of the pouch juice produced by histamine stimulation before, during or after the course of histidine.

II. Secretory response to food in gastric pouch dogs.

In none of the three dogs used in these experiments was there any evidence obtained that the gastric secretory response to food decreased either in volume or acidity after treatment with histidine. To the contrary, in two of the animals studied there occurred an increase in the secretory response to the test meal, due largely to a prolongation of the period during which secretion took place.

In Fig. 2 are presented the results obtained in Dog J which also typify those obtained in Dog E. The pre-histidine control curves for volume and acid response to the meat meal in this dog represent the averages for a two month standardization, and are characteristic of the normal type of secretion curves resulting from food in gastric pouch dogs. Secretion lasts approximately eight hours after feeding, with the peak response during the third to fifth hour. As one might predict, the acid values closely parallel the volume response. This type of food response in dogs is so constant that it may be considered a physiological norm. The pouch in this animal was a moderately large one and secreted around 35 c.c. of juice per hour at the peak response. After the administration of thirty injections of histidine, the period of pouch secretion was prolonged to twelve hours, with peak secretion now occurring between the fifth and seventh hour after feeding. Due to this prolonged secretion, the total volume of pouch juice secreted in response to the meal increased from a pre-histidine value of approximately 150 c.c. to 300 c.c. The acid values continued to follow the volume curve. These changes are clearly shown in Fig. 2. The alterations in the secretory curve were discernible as early as the second week after injections

were started, increased to reach a maximum about two weeks after histidine was stopped, and diminished gradually over the ten months during which observations were continued. The post-histidine secretion curve of pouch dog E was quite similar to that shown in Fig. 2 in respect to the prolongation of the secretory period and the resultant increase in the total volume response to the test meal. After histidine, peak response to feeding occurred nine to eleven hours after feeding and a fasting level was reached only at the fourteenth hour.

The fluoroscopic examinations undertaken in these two dogs, to ascertain whether delayed gastric emptying time was the basis for the protracted post-histidine secretory response to food, were made by mixing sufficient barium sulphate with the standard test meals and screening the animals at intervals. Gastric motility appeared to be within normal limits for dogs, and the stomachs of both the animals were completely empty roentgenologically six hours after feeding. This suggests that gastric secretion continued for about six hours after the stomach had emptied. The inferences drawn from these fluoroscopic studies, however, should be exceedingly guarded, as the procedure required a break in the usual experimental routine to which the dogs were trained. Furthermore, the dogs were fed barium with their test meal, and the emptying time of this type of meal may not be directly comparable to that of the test meal.

The third gastric pouch dog T, with a peak secretion following food reaching at times as high as 150 c.c. of pouch juice per hour, failed entirely to show any notable alteration in gastric secretory response after fifty injections of the amino acid. This dog differed from the other two preparations only in having a very large accessory stomach, and thus requiring supplementary sodium chloride to maintain its electrolyte balance. In Fig. 3 is shown the volume and acid response of this animal before and after histi-

Fig. 4. Gastric secretory response to test meal before and after histidine. Gastrotomized dog A. Weight, 14 kg. Fed 300 grams lean hamburger. Total and free acid values of samplings, collected until stomach empty. Pre-histidine curve plotted from the average of 20 standardization experiments; post-histidine curve, 20 trials. Note delayed gastric emptying, and the lag in appearance time of appreciable amounts of free acid following the administration of histidine.

Fig. 5. Gastric secretory response to test meal before and after histidine. Gastrotomized dog R. Weight, 12 kg. Fed 200 grams lean ground meat. Total and free acid values and per cent solids of gastric samplings, collected until stomach empty. Pre-histidine curve constructed from the average of 25 experimental runs; post-histidine, 12 trials over a period of two months. There is no such delay in gastric emptying time as seen in dog A, Fig. 4.

dine administration, and it is clear that no significant change has occurred. Observations continued at intervals up to six months after injections were stopped did not differ from the values indicated in the post-histidine curves depicted in the figure.

III. Secretory response to food in gastrotomized dogs.

Two gastrotomized dogs were studied in order to obtain a more dynamic picture of any changes in the secretory response to food induced by histidine. This type of preparation enables one to obtain information about the gastric emptying time without the complicating factors of barium meals and fluoroscopy, or passage of stomach tubes. By ascertaining the amount of solid food remaining in the stomach at any given interval after feeding, information is gained concerning the motor as well as the secretory activity of the stomach.

Gastrotomized dog A showed changes after histidine similar to those observed in two pouch dogs. Fig. 4 represents the total and free acid values of the hourly samples taken during the response to the test meal before and after a course of histidine injections. It is apparent that the post-injection secretory response was prolonged four hours, and that there was a delay in the appearance of significant amounts of free acid. Inasmuch as the very late samples still contained some food, it would seem that a delay in gastric emptying time rather than a lag in secretory response accounts for both the prolonged secretion and the late appearance of free acid. These changes were fully evident a short time after completion of the injections, and persisted for the four months during which observations were continued.

Gastrotomized dog R, on the other hand, failed to show any alteration either in emptying time or acidity values after the amino acid. The results in this animal are shown in Fig. 5, which also includes an index of the per cent solids in the gastric samples. No prolongation of secretory period and no delay in the appearance of free HCl occurred.

IV. In vitro experiments.

Isolated strips of rabbit ileum were studied in an organ bath to determine the effects of histidine on the smooth muscle of the enteric tract. The intestinal strips were shown to be reactive not only by the character of the tone and peristalsis exhibited, but also by tests before and after the histidine experiments with acetyl-beta-methyl-choline (1:12,000,000 and 1:6,000,000) and with B-diethyl-aminoethyl-diphenyl acetate hydrochloride (1:2,000,000), which have parasympathetic spasmodic and antispasmodic actions respectively. The results of these tests revealed that histidine produced no discernible effects either on the amplitude or frequency of contractions, or the tonus of the intestinal segments in dilutions which can at all be considered within physiological limits (1:2,000,000 to 1:50,000). Nor did the amino acid have any influence in dilutions as low as 1:10,000. In dilutions of 1:5,000 and below, however, histidine exhibited a moderately inhibitory effect on the amplitude of contraction and the tonus of the intestine, lasting from one to several minutes. In a dilution of 1:500 complete inhibition and loss of tone resulted. The pH of 7.6 of the oxygenated Ringer-Locke solution was altered, however, to a pH of less than 6.0 by the addition of the amount of amino acid necessary to make a dilution of 1:500. These paralytic effects of high concentrations of histidine were readily terminated by washing out the amino acid and restoring the normal bath fluid.

DISCUSSION

It is apparent from the results presented above that the reduction in volume and acidity of gastric secretion in response to food and histamine reported by certain clinical investigators to occur after histidine treatment has not been corroborated in dogs. Indeed, two of three pouch animals and one of two gastrotomized dogs showed an increased and prolonged gastric secretory activity during and for variable periods after histidine injections. The limited number of experimental animals, however, does not allow the conclusion that the amino acid was the direct cause of these secretory changes. If histidine should prove to be the cause, it is not clear why the effect is inconstant, nor is it evident why parenteral histidine should produce this effect in dogs on diets high in adequate protein and therefore high in this amino acid.

Nearly every amino acid has been investigated for its effect on the secretion of gastric juice. The most comprehensive work is that of Ivy and Javols (8) who used twenty pure amino acids in their investigation. Of these, twelve were active, but only when administered orally in relatively large doses. None of them was active in the sense of "gastric secretin" and all were ineffectual when given subcutaneously. Their experiments, however, were acute ones calculated to elicit immediate secretory responses and therefore not designed to detect any such histidine effects as might alter the response to standard food and histamine stimuli.

The results of the in vitro experiments recorded above are confirmatory of the findings of Hirschfelder and Cantwell (7). In addition, these authors have proven that any discernible histidine action is definitely due to pH alterations.

While realizing the difficulty in transferring data obtained in animal experiments to clinical problems, the authors feel that the results reported here afford no support for the therapeutic claims made for this amino acid in the treatment of peptic ulcer in man.

SUMMARY

The effect of intramuscular histidine on gastric secretion was studied in dogs with accessory stomachs

and in gastrostomized preparations. In vitro experiments were performed to determine the action of this amino acid on intestinal tone and motility.

Histidine did not decrease the volume or acidity of gastric secretory response to either food or histamine stimulation. In two of three pouch dogs and in one of two gastrostomized dogs there occurred a prolonged and increased secretory response coincident with histidine administration. In organ baths, histidine in physiological concentrations had no effect on the tone or motility of segments of small intestine. The data presented in the above experiments offer no support for the therapeutic claims made for histidine in the treatment of peptic ulcer in man.

The Use of a New Antispasmodic Drug in Gastro-Enterology

A Preliminary Report

By

MOSES EINHORN, M.D.
NEW YORK, NEW YORK

IN all gastric diseases the symptoms are more or less similar, and appear in the form of heartburn, sour eructation, nausea, vomiting, etc. The outstanding complaint, however, which causes the patient to consult a physician for relief is pain. The pain may come as a mild discomfort or pressing feeling in gastric disorders, a cramp-like pain associated with diarrhea or constipation in intestinal disorders, or a sharp and cutting pain in the right upper quadrant in disorders of the gall bladder. Oftentimes, the pain is not definitely localized, but extends over the entire region of the umbilicus.

Aside from making a provisional diagnosis based on the clinical history and physical findings, or a complete study of the case by X-rays or other laboratory examinations, it is obvious that it is the duty of the physician to consider the welfare of his patient, and give him immediate relief of his pain. Numerous drugs are prescribed for this purpose, various derivatives of Belladonna being most frequently used.

Belladonna contains an active principle in the form

of an alkaloid known as atropine which is insoluble in water. The sulphate of atropine is soluble and is the salt most commonly used. Although this drug relieves the pain, there are certain unpleasant physiological setbacks connected with it, such as flushing of the face, inhibition of the salivary secretion, and dilatation of the pupils, produced in part by a depressant action on the endings of the oculomotor nerve in the iris. Belladonna also quickens the pulse, and may produce an increase of arterial pressure.

In my own practice, I discontinued the use of Atropine Sulphate and Extract of Belladonna, and, in addition to other new antispasmodic drugs, used Tincture of Belladonna, since the individual dose can be obtained more easily without marked unpleasant side effects, by increasing or decreasing the number of drops.

Due to its unpleasant setbacks, the general use of atropine as an antispasmodic was impeded, and numerous efforts were made by various pharmaceutical

houses to find a substance which would give the same antispasmodic effect without the undesirable side-effects.

Recently, a new drug was placed on the market, which I have been using in my practice. I have made a study of this drug on a number of my patients, and shall give herein a preliminary report of my findings from a clinical point of view.

Pharmacological studies of this drug have been made by Dr. Rolf Meier (1) in Europe, and by Drs. Johnson and Reynolds (2) in this city, and below I shall give a summary of their findings, so that the physician may understand the exact status of the pharmacological action of this drug.

According to Meier, this new synthetic preparation, Diphenylacetyldiethylaminoethanolester-hydrochloride has the following structural form:

This preparation is a white crystalline material, readily soluble in water, and is stated to have a melting point of 112 to 114 C. The colorless aqueous solution can be sterilized without any alteration of its properties, and is stable. Dr. Meier claims that this substance belongs to a class of basic esters all characterized by the presence of the diphenylacetyl group, which, by recent pharmacological studies, were found to possess excellent antispasmodic action. The diethylaminoethylester has been claimed by him to be the most satisfactory representative of this group, and was, therefore, selected for therapeutic purposes.

Pharmacologically speaking, the most significant quality of this new compound is that it happens to have pronounced muscular action, as well as a neurotropic effect on the ends of the parasympathetic nerve, when tested on the isolated intestine of the rabbit.

To understand the importance of this fact, it may be recalled that the so-called "antispasmodic" drugs, supposed to give relief in various pathological states characterized by hypertension or increased irritability of the autonomically innervated organs, are theoretically divided according to the points of attack. Thus, in pharmacology, those drugs causing chiefly relaxation of the smooth muscles, after their irritation by specific muscle stimulants like barium salts, are separated from those antagonizing the spastic effect of a number of drugs which stimulate the autonomic parasympathetic nerves, controlling the function of smooth muscles.

In order to determine the pharmacological activity of this substance, Dr. Meier made a number of experiments comparing it with well-known preparations possessing similar properties such as Atropine and Papaverin. The study was made on an isolated segment of the intestine of the rabbit. Of great importance when determining the antispasmodic effect of a given preparation is its action on the intestines in which spasms have been produced artificially by administration of neurotropic or musculotropic stimulants. In the customary manner the neurotropic spasms were produced with acetylcholine while for the induc-

tion of musculotropic spasms barium chloride was used.

In the first set of experiments on isolated intestine of rabbit, spasms were induced by acetylcholine and a comparison of the action of the product with atropine sulphate was made. The result was that the spasm relieving action of this new drug set in following administration of a dose 20 times as large as the dose of atropine required to obtain the same effect. From these experiments it is apparent that the drug has a pronounced antispasmodic action on spasms of neural origin.

In the second set of experiments on isolated intestine of rabbit, musculotropic spasms were induced by barium chloride, and a comparison of the action of the product with Papaverine was made. The following results were obtained: With Papaverine the complete relief from intestinal spasm can only be obtained in the most favorable cases by the use of concentrations of from 10^2 to 5×10^3 , while on the other hand, the new product produces definite results in concentrations of 10^2 , proving that its musculotropic action is at least equal to that of Papaverine. Furthermore, it is important that when the BaCl_2 spasm has been relieved by the drug the spontaneous movements of the intestines are almost completely reestablished, while following the use of Papaverine in doses required to obtain the same effect, complete paralysis generally sets in. These experiments prove that on the isolated intestine of the rabbit the drug combines the paralyzing effect on the parasympathetic nerves with the complete desirable musculotropic action of Papaverine.

A study of the effect of the drug on the iris was also made, and the following results were obtained: A 1% solution on the cat's eye produces only a very slight transitory dilatation of the pupil while dilatation produced by atropine in concentrations as low as .001% is clearly noticeable. The action of atropine is, therefore, 1000 times stronger than that of the drug when tested on the cat's pupil.

Likewise the effect of this drug on the salivary secretion in rabbits following pilocarpine stimulation is much less than that of atropine. It is not possible even with sublethal doses of the new compound to obtain a complete inhibition of salivary secretion.

The pharmacological study of the drug was made in this country by Drs. Johnson and Reynolds (2). In their work they were concerned with three aspects of its pharmacodynamic action, namely, its toxicity, its effects upon the circulatory system and respiratory movements, and its antispasmodic properties on uterine muscle.

Toxicity of the Drug:

The study was made on rabbits and cats and it was found that it is moderately toxic when given intravenously, but intraperitoneally or intramuscularly it is not toxic except when given in excessive amounts. It does not have any appreciable cumulative action and it rapidly loses its toxic properties when injected into the blood stream.

Circulatory and Respiratory Effects:

Experiments were performed on cats, and administered by routes other than intravascular, had no marked circulatory effect and was free of any measurable action on respiratory movements, even when large

amounts of the drug were administered. Intravenously, its effect on blood pressure is depressing but evanescent.

Antispasmodic Action on Uterine Muscle:

(a). *Antagonism to posterior pituitary extracts:* This drug was found to reduce but not abolish the uterine spasms induced by the oxytocic action of pituitrin. This antispasmodic action of the drug was observed to persist for more than an hour, but not for several hours.

(b). *Antagonism to pilocarpine.* The drug was found to inhibit the persistent elevation of tone in uterine muscle which normally follows the injection of pilocarpine. In this respect, the drug is not as wide in its scope of action.

(c). *Antagonism to calcium salts.* It inhibits spasms of the general uterus of the unanesthetized rabbit produced by calcium lactate.

In summary, it may be said, that Johnson, Reynolds and Meier found that this new substance is a drug having pronounced antispasmodic properties. In contrast to atropine, those parasympathetic paralyzing actions which in humans are the cause of unpleasant by-effects, especially pupillary dilatation and inhibition of salivary secretion, are much less pronounced with this drug. Besides this neutral action, it also exhibits the typical muscular action inherent to papaverine.

Dr. U. Salow (3) made a clinical study of this new preparation on 51 patients, 22 of which were gastro-intestinal cases. He obtained good results in 42 of these cases, but no results in the remaining 9 cases.

The preparation was well tolerated by the patients, no matter by which method it was administered. Complaints of unpleasant side-effects were never received, and only a few patients who had received the preparation over a long period, mentioned that they had occasionally felt slight dryness in the mouth.

Dr. F. Nagel of the famous Von Jagic clinic in Vienna (4) also made a clinical study on 56 patients, 33 of which were gastro-intestinal cases. He obtained good results in 27 cases, moderate results in 14 cases, and no results in the remaining 15 cases. He also observed that the side-effects, such as dryness of the mouth, dilatation of the pupils of the eyes, and palpitation of the heart, were not present.

In my own study of this drug in 24 gastro-intestinal cases, covering a period of more than a year, (preliminary report of which is given below), I was concerned mainly with the following: (1) The presence or absence of the side-effects which usually accompany atropine, such as dryness of the mouth, dilatation of the pupils, and circulatory disturbances; (2) its immediate effect on pain.

It is understood that this product was not given alone, but in conjunction with my usual medication, except that this drug was substituted for Tincture of Belladonna.

The cases consisted of the following: eleven duodenal ulcers, one gastric ulcer, one diverticuli of the duodenum, one cardiospasm, three cholecystitis, five colitis (spastic of mucus), one hyperacidity and one acute intestinal obstruction.

The results may be summed up as follows:

1. All the patients were free of side-effects, such as dryness of the mouth, dilatation of the pupils of

the eyes, palpitation of the heart and irregular pulse.

2. No definite relief of pain was reported in the cases of cholecystitis. The results were poor because the pain was intimately associated with the inflammatory process rather than with a spasm, hence logically relief following the use of an antispasmodic could hardly be anticipated. No results were obtained in the cases of cardiospasm, because cardiospasm is a *misnomer* and is not a true spasm of the cardia.

3. Good results were obtained in the remaining cases. The patients were relieved of their pain, although this relief cannot be attributed entirely to the drug, since same was used in conjunction with other medication (diets, alkaline powders, etc.).

4. Excellent results were obtained in certain cases where hiccough was present. This complaint disappeared completely about twenty minutes after administering the drug intramuscularly.

5. There were no toxic effects, even when the drug was administered over a long period of time.

Case 1. Bleeding Duodenal Ulcer—R. R., female, 39. Gastric complaint: Pain two hours after meals, relieved by food and bicarbonate. Attack of *melena* in 1928. Recurrence in 1932, but no *malena*. Free of symptoms until spring 1937, when a second hemorrhage occurred. Roentgen-ray findings: Irregular duodenal bulb. Free HCl: 52; Total 75. Hospitalized and treated with diet, special alkaline powders and Trasentin tablets. Pain disappeared. No side-effects.*

Case 2. Pre-pyloric Duodenal Ulcer—M. S., male, 33. Gastric complaint: Abdominal pain for first time in 1927. Hemorrhage in 1929. Recurrence in 1934, and nearly every six months thereafter, usually in the spring and fall. Recently, recurrences more frequent, with loss of weight and occasional vomiting of blood. Roentgen-ray findings: Pre-pyloric and duodenal ulcer. Free HCl: 35; Total 70. Patient placed on medical ambulatory treatment, consisting of diet, powders and Trasentin tablets. Symptoms quickly disappeared, condition improved, and patient gained weight. No side-effects.

Case 3. Spastic Colitis—B. F., male, 38. Gastric complaint: Pain in epigastric region 3-4 hours after meals, usually along the transverse and descending colon. Roentgen-ray findings: No abnormal findings of stomach or duodenum. Twenty-four hour examination revealed all the barium evacuated. Barium enema showed spasticity throughout the descending colon and sigmoid. Sigmoidoscopic examination negative. Free HCl: 20; Total 46. Patient placed on a colitis routine, consisting of special diet, Kaolin powder and Trasentin tablets. Pain disappeared. No side-effects.

Case 4. Duodenal Ulcer—J. S., male, 24. Gastric complaint: Pain 2 hours after meals, relieved by alkaline powders or milk and cream. Roentgen-ray findings: Irregular duodenal bulb. Free HCl: 32; Total 54. Appendectomy was done in the fall of 1936, as it was believed that the complaint was due to a pathological appendix, but the symptoms were present even after the operation. Patient was hospitalized, and the routine treatment with Trasentin tablets was given. Symptoms disappeared, and there were no side-effects.

Case 5. Cholecystitis and Spastic Colitis—F. M., female, 44. Gastric complaint: Pain in epigastric region, also along the left upper and lower quadrants of the abdomen, usually $\frac{1}{2}$ hour after meals; also before and during bowel movement. Intermittent constipation and diarrhea. No vomiting and no loss of weight. Enemas had a tendency

*Side-effects: Dryness of the mouth, dilatation of the pupils of the eyes, circulatory disturbances such as palpitation of the heart and irregular pulse.

to aggravate the pain along the left lower quadrant of the abdomen. Roentgen-ray findings: No abnormal findings of the stomach or duodenum. Barium enema showed a spasticity throughout the descending colon and sigmoid. No visualization of the gall bladder. Free HCl: 62; Total 92. Patient treated with diet and Trasentin tablets. The abdominal pain did not disappear and the results were not satisfactory in this case. No side-effects.

Case 6. *Duodenal Ulcer*—Rev. E. Z., male, 45. Gastric complaint: Pain in the epigastric region radiating to the back, usually 1-2 hours after meals. Relieved by food and bicarbonate. Recurrences usually in the spring and fall. Roentgen-ray findings: Duodenal bulb irregularly filled. Free HCl: 55; Total 75. Patient placed on medical ambulatory treatment (diet, special alkaline powders and Trasentin tablets). Symptoms disappeared. No side-effects.

Case 7. *Penetrating Gastric Ulcer*—B. B., female, 49. Gastric complaint: Pain in epigastric region immediately after, or 2-3 hours after meals, radiating also to the back. The pain is gripping and burning in character, and remains until the patient is relieved by vomiting. The vomitus was previously only stained with blood, but lately contained pure blood. Recently, patient had pain immediately after meals, accompanied by hiccoughs. At first the hiccoughs came only intermittently, but later they became continuous. There were no hiccoughs when the patient did not take any food. She suffered with these symptoms for a period of two years, and they reappeared six months ago, and then three months ago, and lately became more frequent. Patient was hospitalized twice before reporting to my office, and was previously treated for cholecystitis. When patient came under my care, she had lost about 15 pounds. The roentgen-ray findings revealed a penetrating gastric ulcer on the posterior wall about 1½ inches below the cardia. Hospitalized for a period of three weeks, and fed through a tube. Trasentin tablets and ampoules were given, and later patient was placed on an ulcer diet. The hiccoughs and the vomiting stopped. Condition improved, gained weight, and recovered completely. No side-effects. Also no toxic effects when large dose of Trasentin were given.

Case 8. *Cardiospasm*—I. K., male, 44. Gastric complaint: Pressing feeling in the chest, and difficulty in swallowing. Roentgen-ray findings: Cardiospasm. Injections of Trasentin proved unsatisfactory, and the patient was treated by gastric feeding and dilatation by special dilating apparatus. The so-called cardiospasm is not a spasm of the cardia, but is more of a cardiologic in nature, with a disturbance in the opening and closing of the cardia. The Trasentin therefore, had no effect on this condition. No side-effects.

Case 9. *Cholecystitis*—M. Y., female, 56. Gastric complaint: During the past two years, patient had intermittent attacks of pain in the right upper quadrant of the abdomen, radiating to the right shoulder; also attacks of hiccoughs. Roentgen-ray findings: Examination done elsewhere, revealed a faint visualization of the gall bladder. Patient was placed on a special diet, and Trasentin tablets were given. The pain was reduced, but did not disappear entirely, and the hiccoughs disappeared completely. No side-effects.

Case 10. *Duodenal Ulcer*—J. G., male, 42. Gastric complaint: Pain in epigastric region 2-3 hours after meals, relieved by food and bicarbonate; also night pain. Free HCl: 50; Total 66. Roentgen-ray findings: Irregular duodenal bulb. Patient was hospitalized, and treated with ulcer diet, and Trasentin tablets. The symptoms disappeared and he gained weight. No side-effects.

Case 11. *Spastic Colitis*—Dr. A. G., male, 41. Gastric complaint: Pain along the descending colon, usually with bowel-movement. First time in 1931. Intermittent diar-

rhea and constipation. Barium enema shows spasticity throughout the colon, particularly the descending colon. Patient placed on soft diet and Trasentin tablets. Symptoms disappeared, the bowels became regular. No side-effects.

Case 12. *Duodenal Ulcer*—J. M. T., male, 38. Gastric complaint: Pain in the epigastrium 2-3 hours after meals, relieved by hot drink or bicarbonate. Same complaint a year ago. Free HCl: 35; Total 47. Roentgen-ray findings: Duodenal ulcer with niche on the inner border. Hospitalized and treated with ulcer diet and Trasentin tablets. Symptoms disappeared. No side-effects.

Case 13. *Duodenal Ulcer*—J. B., male, 54. Gastric complaint: Pressing feeling and fullness in the chest and epigastric region. No definite relation to meals, and usually more aggravated in the morning. Same complaint 15 years ago, 8 years ago, and again during the past year. About a year ago a general practitioner diagnosed the case as coronary artery disease, although the electrocardiograph was negative. Roentgen-ray findings: Irregular duodenal bulb, with a niche at the base of the inner border of the bulb. Also diverticuli along the descending colon. Free HCl: 27; Total 52. Patient was hospitalized and treated with an ulcer diet and Trasentin tablets and ampoules. Symptoms disappeared. No side-effects.

Case 14. *Duodenal Ulcer*—S. K., male, 34. Gastric complaint: Pain along the umbilical region and the right upper quadrant of the abdomen, usually after meals, also night pain. Relieved by food and bicarbonate. Appendectomy in 1931 but patient had the same recurrences in 1933, 1935 and 1936. Roentgen-ray findings: Irregular duodenal bulb. Patient was hospitalized and placed on an ulcer diet with alkaline powders and Trasentin tablets. Symptoms disappeared. No side-effects.

Case 15. *Mucous Colitis*—M. D., female, 43. Gastric complaint: Discomfort and annoying feeling over the entire abdomen. No relation to meals, but associated with the bowel movement. Bowels loose, with large amount of mucus. Barium enema revealed very irritable and spastic colon. Patient was placed on a colitis diet, with anti-diarrheal powders and Trasentin tablets. The diarrhea stopped, the pain disappeared, and there were no side-effects.

Case 16. *Duodenal Ulcer*—B. W., female, 44. Gastric complaint: Cramps 3-4 hours after meals. Relieved by food and bicarbonate. Heartburn. Patient previously treated for an ulcer. Roentgen-ray findings: Irregular duodenal bulb. Cholecystographic examination negative. Free HCl: 35; Total 60. Patient was placed on a ambulatory treatment, and alkaline powders and Trasentin tablets were given. Symptoms disappeared and there were no side-effects.

Case 17. *Duodenal Ulcer*—J. M., male, 41. Gastric complaint: Pain in epigastric region two hours after meals. Relieved by alkaline powders and food. Severe night pain and heartburn. Roentgen-ray findings: Irregular duodenal bulb. Intermittent recurrences for past ten years. Last attack quite severe, and patient was therefore hospitalized and treated with the drip method. Trasentin tablets and ampoules. Symptoms disappeared entirely. No side-effects.

Case 18. *Duodenal Ulcer*—L. E., male, 39. Gastric complaint: Discomfort in the epigastric region about 1-1½ hours after meals. Relieved by alkaline powders and food. Intermittent recurrences for past few years, in the spring and fall. Roentgen-ray findings: Irregular duodenal bulb. Free HCl: 30; Total 60. Patient was placed on a diet, alkaline powders and Trasentin tablets. Symptoms disappeared and there were no side-effects.

Case 19. *Hyperchlorhydria*—M. L., male, 21. Gastric complaint: Pressing feeling and fullness in the epigastric

region and the chest. Relieved by belching. Occasional hiccoughs, heartburn and sour eructation. No abdominal pain. Roentgen-ray findings: Fluoroscopically, pylorospasm for 15 minutes; otherwise, negative. Free HCl: 57; Total 70. Patient was treated with alkaline powders, Trasentin tablets and ampoules. Symptoms disappeared. No side-effects. Patient was X-rayed again at a later date and no pylorospasm present.

Case 20. *Mucus Colitis*—L. B., female, 35. Gastric complaint: Pain over entire region of the abdomen, particularly with bowel movement. Intermittent constipation and diarrhea, and mucus with the bowels. Proctosigmoidoscopic examination revealed a large amount of mucus present in the rectum and sigmoid. Barium enema examination showed spasticity throughout the colon. Patient was placed on a colitis diet and Trasentin tablets. The bowel movement was regulated, the pain disappeared, and there was less mucus with the bowels. X-ray examination done at a later period, revealed less spasticity throughout the colon. No side-effects.

Case 21. *Acute Intestinal Obstruction*—R. M., female, 40. Gastric complaint: Acute cramps over the entire abdomen, particularly in the right upper and lower quadrant. Cholecystectomy and appendectomy July 11, 1936, and numerous small biliary calculi found in the gall bladder. Patient felt well for about 18 months, but then suddenly was seized with severe cramp-like pains in the lower right quadrant of the abdomen. The cramps came at intervals of every five minutes. Patient vomited fecal matter. Diagnosis of acute intestinal obstruction was made, and 1½ c.c. Trasentin ampoule was given to relieve the pain. Pain subsided after a period of about 20 minutes. Patient was removed to the hospital and operated on, releasing a band which had formed across the small intestines.

Case 22. *Cholecystitis*—E. W., female, 52. Gastric complaint: Occasional pain during the past ten years in the right upper quadrant. Attack with jaundice eight years ago. Five years ago another attack, but no jaundice. Lately the attacks became more frequent. Roentgen-ray findings: G.I. Series: Negative. No visualization of the gall bladder. Patient was placed on a gall bladder diet and Trasentin tablets. The pain disappeared, and her condition improved. No side-effects.

Case 23. *Diverticuli of the Duodenum*—A. A., female, 32. Gastric complaint: Pain commenced at the age of

twelve. Intermittent pain throughout adolescence, coming at more frequent intervals as she grew older. Patient was X-rayed in 1927, and the examination revealed diverticuli of the duodenum. Was operated on that same year, and a superior and inferior diverticuli with inflammatory reaction was found distal to the pyloric ring. A gastroenterectomy was done with no exclusion of the pylorus. Patient felt well for a period of five years, then since 1936 recurrent attacks of pain. X-ray examination revealed the barium passing through the new opening, but also some passing through the pylorus. Patient was hospitalized and placed on an ulcer diet, Trasentin tablets and ampoules. The pain disappeared and her condition improved. No side-effects.

Case 24. *Duodenal Ulcer*—E. B., female, 28. Gastric complaint: Pain in the epigastric region, 2-3 hours after meals; also night pain. Relieved by food and bicarbonate. Same complaint a year ago. Roentgen-ray findings: Irregular duodenal bulb. Patient was placed on an ulcer diet and Trasentin tablets. Pain disappeared and the condition improved. No side-effects.

SUMMARY

A new antispasmodic drug was used in 24 G.I. cases. All were free of side-effects such as dryness of the mouth, dilatation of the pupils and palpitation of the heart. Relief of pain was obtained in most cases after administering the drug. Also, particularly good results were obtained in cases where hiccough was present.

The above is only a preliminary report, and at a later date the study of the drug will be continued, along the following lines:

1. Its immediate effect in attacks of biliary colic.
2. Its effect in cases of pylorospasm.
3. Further study in cases of spastic colitis.

I wish to express my gratitude to Mr. L. T. Hilcorn, President of Clay-Adams Co., for his kind cooperation in the development of my tube.

FACTORS WHICH INFLUENCE THE REGENERATION OF BLOOD FOLLOWING HEMORRHAGE FROM PEPTIC ULCER

MANY clinicians have accepted as more or less inevitable the prolonged convalescence which often follows moderate or severe bleeding from peptic ulcer. One of the most significant factors contributing to the slow recovery of the patients is the delay in restoration of the blood to normal values which is due, in many cases, to depletion of stores of iron as a result of chronic loss of blood. For many years the treatment of patients with bleeding peptic ulcer has consisted principally of a few days of starvation followed by a very limited intake of food and the frequent use of alkalies, all of which appears now in the light of our present knowledge to have tended further to retard convalescence.

If recovery from bleeding is to be rapid it is essen-

tial to have available in the diet in abundant quantities such substances as iron and protein, which are necessary for regeneration of the blood. Consideration also must be given to those factors which may influence the absorption of iron and other essential substances from the gastro-intestinal tract. Studies within the past few years have made available information about these factors which should prove of great practical value in reducing the usual period of disability from bleeding.

Whipple and his coworkers have shown clearly that foods such as liver, kidney, gizzard, spleen and pancreas, are the most potent in stimulating the production of new hemoglobin in dogs rendered anemic by bleeding. Of various inorganic elements, iron was found to be the most effective in the production of new hemoglobin.

Other important factors in maintaining the blood at normal levels include the intrinsic substance of

Castle, certain amino-acids, copper, vitamin C, and some components of the vitamin B complex.

Within the past two years Meulengracht has reported the results of his use of "treatment with food" as contrasted to "treatment with starvation" of patients with bleeding from ulcer. Using a full purée diet and iron medication he reported not only a shorter convalescence from the period of shock but a considerably reduced mortality among those patients with actively bleeding peptic ulcers. These observations have done much to stimulate others to use this form of treatment. If clinical experience should show that this method of treatment is safe in most cases, much may be accomplished in the future in shortening the period of convalescence from bleeding.

Recent emphasis on the rôle of the gastro-intestinal tract in the predisposing to or conditioning of deficiency diseases has focused our attention on the importance of such a factor as gastric acidity in the utilization and absorption of the products of digestion. The impairment of utilization of iron in some patients with achlorhydria has been recognized for some years and has led to the very interesting observations of Kellogg and Mettler that alkaline therapy used in the treatment of peptic ulcer apparently interferes with the utilization of dietary iron. These observers made careful studies of the blood of four patients with anemia secondary to prolonged loss of blood from peptic ulcer. Observations were made of the changes which may take place in the formation of blood as a result of the administration of a diet rich in iron during periods in which the upper part of the gastro-intestinal tract was made alkaline by a modified Sippy regimen and after the alkaline therapy was discontinued. It was demonstrated that a diet rich in iron had practically no effect on the formation of hemoglobin during the period of alkalization. However, after the administration of alkalis was stopped, there was a marked improvement in the blood, with reticulocytosis and a subsequent increase in the concentration of the hemoglobin. The increase in number of erythrocytes in the blood was comparable to that produced by adequate therapy with inorganic iron. During periods of administration of a diet rich in iron and alkalization in which the concentration of hemoglobin did not rise appreciably, there was observed a slight but consistent increase in the number of erythrocytes in the blood, the result, presumably, of the absorption of some substances necessary for the formation of cell stroma or for the maturation of erythrocytes. The possibility that achlorhydria or alkalization may significantly interfere with absorption of other essential hematopoietic factors is indicated by the studies of Einhauser, who has pointed out that utilization of test doses of vitamin C by patients with achlorhydria is disturbed because of inadequate absorption. These observations on the influence of alkalization of the upper portion of the intestinal tract on the absorption of iron and vitamin C suggest that patients with anemia resulting from bleeding are likely to remain anemic until alkalization is discontinued or until large doses of inorganic iron, and in some cases perhaps vitamin C, are given.

As a result of these considerations, in the treatment of patients who have recently bled from peptic ulcer it seems wise for the physician to remember those foods which have been shown to be potent and essential in the regeneration of the blood, to see that the

patient receives them in adequate amounts in a form compatible with comfort and rapid recovery and, lastly, to take into consideration those conditions which may interfere with the function of the gastro-intestinal tract, particularly with regard to changes in its chemical reaction following the administration of alkalis.

Dwight L. Wilbur, San Francisco, Calif.

IS THERE A TREATMENT FOR HEPATIC INSUFFICIENCY?

IN spite of a growing knowledge of liver disease the physician is still powerless to combat severe hepatic damage. Furthermore, there has been no reliable method of differentiating between a liver damage from which recovery may be expected, and one which will lead to death. However, Shapiro, McNealy and Melnick (1) in a study of 700 jaundice cases found that a prognosis could be based on the changes in the Ivy bleeding time, which reflects the hemorrhagic tendency in these patients. If the bleeding time became progressively more prolonged, or failed to return to normal after a week of Viosterol administration, then death from hepatic insufficiency or hemorrhage was almost certain, in spite of all available measures taken to aid the patient. This work has recently been confirmed in detail by Boys (2).

Still another possible means of prognosis has been developed recently, based on the cholesteryl ester level of the blood. Epstein and Greenspan (3) determined the cholesterol partition of the blood in over 500 patients with liver disease. In biliary obstruction they found the cholesteryl esters to be elevated, paralleling the degree of icterus. In parenchymatous degeneration, on the other hand, the cholesteryl esters fell in proportion to the severity of the hepatic involvement. In severe yellow atrophy the esters even disappeared from the blood. The determination of cholesteryl esters, they state, has helped materially as an aid in prognosis. Patients with an apparently hopeless clinical outlook and rising ester levels have improved, and conversely, those with apparently mild disease and steadily falling ester levels have gone on to yellow atrophy of the liver and death.

Although methods which apparently permit a more dependable prognosis, are therefore now available, there is as yet no treatment which can arrest the progress of hepatic degeneration. However, the association of decreasing cholesteryl esters with ultimately fatal hepatic insufficiency in clinical cases, may provide a useful lead to a rational therapy. It has been known for many years that depancreatized dogs maintained on a diet without raw pancreas, develop a progressive fatty degeneration of the liver, resulting eventually in death. Chaikoff and Kaplan (4) have shown that this liver damage is associated with a progressive fall in cholesteryl esters of the blood with a correspondingly increased deposition in the liver. This alteration in distribution of cholesteryl can be prevented by the inclusion of raw pancreas in the diet of these animals. What is more important, after the condition is far advanced, the administration of raw pancreas will rapidly restore the normal cholesteryl partition, and relieve the hepatic damage (5). It has been shown by Best and his co-workers (6) that the active constituent of raw pancreas is choline. Choline

is easily available, it is active by mouth, and comparatively non-toxic. One wonders whether it may not be of value in treating clinical liver damage.

This is not the only new possibility in the treatment of these patients. For years, Sato, a Japanese worker, has claimed that an extract of the liver is able to protect the liver from various hepatic poisons. Nothing, however, has been done elsewhere along this line until recently, when Forbes, Neale and Scherer (7) found that an extract of the liver was very effective in protecting the livers of rats against the degeneration produced by chloroform and carbon tetrachloride administered either subcutaneously or by inhalation. Recently Neale (8) has reported that the active constituent of these extracts is sodium xanthate, a purine compound. Unlike calcium, which has been reported to decrease the toxic symptoms produced by carbon tetrachloride and chloroform, without preventing liver degeneration (9), sodium xanthate is reported to prevent almost completely the degenerative processes in the hepatic cells. The compound is much superior to glucose in its protective action on the liver.

The above work with choline and sodium xanthate is still in the animal-experimentation stage. It is not necessarily true that choline, because it will benefit experimentally produced fatty livers in animals will also be effective in curing clinical liver damage. Furthermore, the evidence is not clear that sodium xanthate is as effective in curing as in preventing liver necrosis. Nevertheless, one can't resist the suggestion that these agents should be investigated with the view of providing a possible treatment for otherwise hopeless cases of hepatic insufficiency.

THE PHILOSOPHY OF THE DIABETIC LIFE

"MY diabetic physicians under the age of 40 have less than one-fourth the mortality of all my diabetic patients of similar age; those between 40 and 59 years have less than one-half the mortality as compared with their corresponding age group, and even above 60 the physician does better. My diabetic physicians are a living indictment of the inadequacy of my diabetic treatment. Must a diabetic person become a physician if he wants to live? If you do not think so, then you must teach the patient all the diabetic tricks of the trade." Thus spoke Joslin (1) recently in an article on protamine insulin. One of the "tricks" of the diabetic trade, not infrequently overlooked and neglected is teaching the patient the philosophy of the diabetic life.

Teaching the patient the right philosophy is the fundamental problem in the treatment of any chronic disease. This statement applies more specifically to diabetes mellitus than to other chronic diseases because of the better prognosis. Results of treatment of this condition are dependent upon a faithful continuity in details of treatment but unless the diabetic

patient develops a desirable philosophy, long time control of the disease is seldom consistent. There is an obvious need at the present time to regard the problem of diabetic treatment in a broader sense, to emphasize this apparently abstract phase of diabetic management. Joslin's statement affords abundant proof of this need.

Just what is this diabetic philosophy? It is a state of mind, a way of looking at the present and future and a practical understanding of the principles and details which underlie successful diabetic control. In the words of Osler it is "A Way of Life."

The physician who teaches this philosophy must be first acquainted with the fact that the diabetes of today is a "new diabetes." Joslin is responsible for the term "the new diabetes," and there are ample reasons to justify its use. Outstanding among them are the status of the adequately treated diabetic child, the lengthening of life of the diabetic from an average of a little over six years to almost 16 years, the practical disappearance of diabetic coma as a cause of death and the appearance of cardio-vascular complications as an increasing factor in mortality. The physician must also realize that the "new" diabetic child grows up, goes places and does things. He engages in athletic activity, plans his life work, gets married and perhaps has a family, and if he has been properly informed does not marry another diabetic or into a diabetic family. It should be obvious to the physician that such a person is exposed to the same physical and psychic traumas as his non-diabetic contemporaries, but with this difference, that these traumas frequently precipitate diabetic emergencies. Training the patient to meet these emergencies as they arise or to anticipate them is the duty of the physician.

The physician when he attempts to teach the patient the proper philosophy must also appreciate the importance of other factors which influence success or failure. Most important are the character, mentality and psychic behavior of the individual. Of lesser importance are the patient's family, his friends and business associates, his physician and possibly of least importance the character of the diabetes.

The Patient—The foundation for a proper diabetic philosophy is eradication of fear in the patient, assurance that restoration of normal weight, strength and ability to resume his former economic and social position is practicable and that a normal life expectancy may be anticipated provided he learns to live the rules consistently. In the absence of diabetic complications he should be instructed that they will not develop in the presence of controlled diabetes. In a diabetes of long duration where complications already exist the patient not infrequently has consulted his physician because of them and may be discouraged to the point of doing nothing constructive. Such a person should be reassured there is reason to believe that further progress of his complications can be prevented by good diabetic control.

We see several different attitudes toward the disease among our diabetic patients. The most common is discouragement. The patient who shows this behavior needs to be convinced that the diabetic ideal can be realized. He must be encouraged to resume all activities consistent with his physical capabilities. There is a certain danger in a person of this type that he may permit the care of the diabetes to dominate

his life and activities to the extent of hampering his normal social and economic efficiency. Other patients show resentment because they have developed the disease. Still others assume an attitude of resignation. Another group of patients does not have sufficient respect for the disease, either because the disease is mild or because they have become so well on account of treatment that over-confidence develops to the point that they pay little attention to diet, insulin dosage or urine tests. How to teach these different types of individuals the proper respect for the disease and confidence in their futures will tax the art of the physician. Personal conferences, and group instruction are equally essential.

The Members of His Family—We feel that the best results in treatment are obtained if at least one member of the patient's family is given a practical knowledge of the disease and its control. Pity and sympathy for him should be prohibited. Having a controlled diabetes is no excuse to shirk necessary duties and responsibilities. A physical inferiority complex can develop easily when given a little encouragement. A diabetic child should not be regarded or treated by members of his family as a sick child but should be disciplined in the same way as any other child. He should be trained as he grows older to assume more and more the responsibility for his own care.

His Friends and Business Associates—It is our opinion that for the most part it is a good policy for diabetics not to reveal to other than members of their immediate family the fact that they have diabetes. This prevents the patient being catalogued by his friends or acquaintances as a different or queer person and in many instances avoids an unfavorable appraisal by his employer of his economic value. He also saves himself the embarrassment of answering needless questions from thoughtless persons, such as, "aren't you afraid of forming a habit of taking those insulin injections?", "will you have to take them the rest of your life?", and others in similar vein. These experiences tend to put the patient on the defensive and are apt to break down his morale. By not publicizing his condition he may avoid also the experience of receiving and wondering about the propaganda of diabetic "cures." It is pretty well established as a fact that the names and addresses of diabetic patients are frequently sent with the best of intentions to quack drug manufacturing companies by the friends of the patient.

The Physician—There is yet a necessity for a considerable amount of education of the members of our profession. Some physicians are still thinking in terms of the diabetes of 1921. There are even a few who still advise patients not to take insulin. In this group archaic diet slips dispensed by drug manufacturing houses are still being handed to patients. We need to set up in our own minds higher standards of health and ideals of treatment for the patient, if we shall hope to instill in the patients' minds these same standards.

The Character of the Disease—The character of

the diabetes has relatively little to do with the attainment of the diabetic ideal. The establishment of the proper diabetic philosophy is the important factor. It should be born in mind that the preceding discussion applies to individuals who have only recently developed diabetes and not to the group of persons who have had an uncontrolled diabetes for a number of years and have developed serious complications.

With all these factors in our minds and gradually creating an understanding of them in the mind of the patient we must carry out the technical training. The primary principle of this training is the necessity of making it practicable for the patient to control the diabetes under widely different environments of living and working. Unless this principle is permitted to dominate the program we shall fail in our efforts to teach the patient the proper philosophy.

The technical education should consist of dietetic arithmetic, urine tests and administration and adjustment of the insulin dose. Food values should be learned until they are as usable as the multiplication table. Diet calculation should be practiced until it is possible for the patient to calculate a meal in from 2 to 3 minutes. Food should be weighed at home to keep the eye in training in order that when the patient is away from home he can visualize food portions accurately. The patient should be made to regard the making of urine tests and the taking of insulin in the same light as the daily routine of brushing the teeth or bathing. The adjustment of the insulin dose with variations in physical activity or infection should be taught until the patient develops what we like to call an "insulin consciousness." By this we mean that he should develop the habit of stopping a moment to think before taking insulin whether or not, for example, he plans to do extra work or take additional exercise that particular day.

We have spoken before of the danger of some people becoming slaves to this routine and permitting it to occupy too much of their time and thought. An hour daily is ample time for these duties and many expert persons use less but it requires patience and systematic planning to develop this degree of efficiency. A cheerful acceptance of the situation is the most desirable attitude. It can be pointed out to the patient, however, that there is a peace of mind that comes to the patient who knows every day the status of his diabetes and who is therefore ready for all emergencies.

Equipped with practical information which he uses each day, free from fear of diabetes or his future, with no resentment over his lot, the diabetic is in the best possible condition for the realization of the diabetic ideal. Such a person cannot then be classified as a chronic patient. Diabetics attaining these ideals are about us on all sides. There should be more of them. There will be more of them when the members of the medical profession appreciate more keenly their responsibility in teaching the philosophy of the diabetic life.

MOON, VIRGIL H.

Shock, Its Mechanism and Pathology. Arch. Path., 24:5-642, Nov., 1937 and 24:6-794, Dec., 1937.

"Shock is a deficiency in the circulation, not cardiac and not vasomotor in origin, characterized by decreased total blood volume, decreased volume flow and by hemoconcentration." The author gives in general review the history of the concept of the phenomenon of shock and critically analyzes the many factors, experimental and clinical, known today that have tended slowly to unravel the mystery of this confused subject. He has tried to correlate logically these different factors and place them in a composite interrelated whole—which he expresses briefly in the above quoted definition.

There are certain features of shock now generally accepted to be fundamental; namely, that the heart is not primarily at fault, that the origin does not lie in the vasomotor system, that there is a decrease in the total blood volume and an increase in the concentration of the blood, and that the volume flow of arterial blood—the volume output of the heart per minute—is markedly decreased. Other features not fundamental are regularly associated with shock: namely, anoxemia, lowered alkali reserve (except in shock following intestinal obstruction), lowered basal metabolism, decreased blood chlorides and increased lactic acid, glycogen and nonprotein blood content. Other features are variable: there are variations in the white blood cell count, in temperature, in vomiting, diarrhea, and the presence of blood in vomitus and feces.

The pathologic changes seen in the viscera in all forms of shock, as studied by Moon and his associates, seem to be universally as follows: the superficial veins are collapsed and bloodless, the heart blood and that in large vessels and organs is dark, thick and unclotted. The surface of organs have a purplish cast, the serous surfaces are congested and cyanotic. There are ecchymoses and the cavities contain blood tinged fluid. The bowels are atonic, distended, the mesenteric vessels engorged. The mucosae are congested and edematous, often with ecchymoses. They resemble purple velvet. The lungs are mottled with congestion, the capillaries and venules dilated and packed with blood corpuscles. Capillary hemorrhages are numerous. Edema is present. The liver and kidneys are deeply congested. Blood drips from the cut surface. The spleen, however, contains less blood than normal. It is contracted and the cut surface dry. The heart is cyanotic in color, the vessels engorged. The ad-

renal glands show no special changes. The meninges are wet with occasional punctate hemorrhages.

In several experiments the author injected a neutral solution of trypan blue intravenously into shocked animals. The colloidal dye is retained in the blood under normal conditions, but it passes into the tissues if the permeability of the capillary walls is increased. After death of the animals mucous and serous surfaces of the organs were found deeply blue, as was the fluid in the serous cavities.

The above pathologic changes were found in all cases of shock no matter how produced. They were interpreted

as indicating a loss of tonus of the capillaries and venules systemically, with stasis and increased vascular capacity of the vascular system. The edema indicated increased capillary permeability. Combined these factors account for the decreases in blood volume and for the hemoconcentration.

Shock may be differentiated from hemorrhage by the pathologic picture. The blood in the latter condition is diluted, the viscera are pale and ischemic, the tissues dry. In shock the blood is concentrated, the viscera are congested, the minute vessels engorged and the tissues are edematous. In man and in experimental animals the con-

Roche announces VI-PENTA PERLES

A SUPERIOR PAN-VITAMIN PREPARATION

The perles are tiny—actually smallest in size, and yet highest in potency. Note particularly that Vi-Penta Perles are unusually rich in Vitamins A, B, and C. They contain $1\frac{1}{2}$ times the amount of A, twice the amount of B₁, and $2\frac{1}{2}$ times the amount of C, as compared with similar capsules put up by reputable manufacturers. Packages: boxes of 25 and 100; for hospitals, bottles of 1000.

sicians on request.

gestion and edema of the lungs in shock from any cause often passes into true pneumonia, and may be the mechanism of terminal pneumonia in man.

The deficiency of the circulation in shock tends to become irreversible. If the blood pressure remains below 70 to 80 mm. of mercury for several hours the condition acquires a self-perpetuating quality and progresses. A stage is reached at which neither the body's physiologic reactions nor any known therapeutic measures are effective. A vicious circle is produced into which many diverse agents enter to continue the process. Starting the mechanism of shock with capillary atony (caused by

many and varied agents) the author establishes the sequence of events in the following order: capillary atony—reduced blood volume—reduced blood flow—deficient delivery of oxygen—tissue anoxia—deficient oxidation—acidosis—defective metabolism—capillary atony. The cycle may be initiated at other points than that of capillary atony. Hemorrhage may reduce blood volume sufficiently to produce anoxia, which, by causing capillary atony, will perpetuate the deficiency in the circulation. A loss of hemoglobin to 25 per cent may be restored immediately by transfusion, but with a few hours delay transfusion is ineffective; a n irreversible stage has been reached.

Finally, in resume the author discards various explanations of shock and gives the reasons therefore. The theory of vasomotor exhaustion is untenable; the heart, arteries and the nerve agencies controlling their action are not primarily involved. Acapnia does not explain and fat embolism is a different entity. Lowered alkali reserve is a result rather than a cause of the circulatory deficiency. Substances absorbed from injured tissues and many other agents—metabolic, chemical, bacterial, etc.—produce progressive circulatory deficiency by their effects on the minute vessels in systemic areas. Under the influence of these substances the capillaries and venules become atonic and dilated and their walls abnormally permeable to the fluids of the blood. This results in stasis and leakage of fluid from the vessels. It increases the volume capacity of the vascular system, reduces the total volume and the volume flow of the blood, increases its concentration and produces edema. Shock, in other words, like other conditions of disease, is accompanied by morphologic changes etiologically related to its mechanism of origin.

N. W. Jones, Portland.

Your Anti-Rheumatic Prescription

Now Made More Convenient, Better Tolerated, More Acceptable to Your Patients by
EFFERVESCENCE—ALKALI BUFFERS

Two standard anti-rheumatic medicaments have been combined with an alkaline base in the convenient form of a palatable, effervescent tablet—

SALICI-VESS

Each tablet contains sodium salicylate $7\frac{1}{2}$ grs., sodium iodide 1 gr., citric acid 17 grs., sodium bicarbonate 25 grs.

SUPPLIED IN TUBES OF 30 TABLETS

Why Effervescence:

Helps prevent stomach irritation, encourages rapid assimilation, insures greater ease of administration.

Why Alkali Buffers:

Help protect against gastric upset and combat mild acidotic condition so frequently associated with rheumatic affections.

MCFETRIDGE, ELIZABETH M.

"The Role of Liver Damage in the Mortality of Surgical Diseases."
South. Med. Jour., 31:35-39, Jan., 1938.

The importance of the liver as a site of medical or surgical disease is quite well recognized. Consideration of it as in the background of every surgical disease is a new conception and suggests the advisability of routinely determining the state of liver function preoperatively as one does the condition of the heart, lungs and kidneys. Post-operative liver deaths fall into one of the three groups. In the first place there are those presenting a toxic or infectious change secondary to the primary cause of illness. This is not due to a primary biliary deficiency. The second group includes the dramatic liver or liver-kidney deaths. The patient usually dies in twenty-four to forty-eight hours after operation with marked hyperphrexia or seven to fourteen days later with urinary symptoms predominating. These are true instances of liver failure and autopsy findings show degeneration or necrosis of the liver plus, in the delayed deaths, similar changes in the convoluted tubules of the kidney. It is probable here that previously damaged livers have no reserve margin of safety and when subjected to the additional strain of trauma and surgery fail in the normal function of detoxification, undergo necrotic change themselves and release increased toxic material into

As One Gastroenterologist To Another

A Gastroenterologist of International renown has declared, "By degrees we have been convinced that constipation is a multiple deficiency disease. Evidently the multiplicity of factors involved in intestinal disease, requires a multiple therapy Even grave cases of intestinal dysfunction can be controlled by a complete intestinal therapy without the use of laxatives and purgatives."

The New Physiologic Approach Has Been Found

NOW as never before, is there available a comprehensive and combined multiple therapy, which goes to the bottom of gastrointestinal dysfunction, overcomes it, by restoring interdependent co-operation of associated organs and reactivating interrelated functional synergy.

the circulation with subsequent kidney damage. The third group of cases which have the same pathological picture as just described are those associated with mechanical trauma to the liver as by stab or gunshot wounds. The clinical importance of this observation is that it is probably better to resect crushed areas than to risk hepatic necrosis.

Liver deaths similar to those just described have been demonstrated in toxic thyroid disease, intestinal obstruction, pancreatic disease, and ap-

pendicitis. It would, therefore, seem apparent that evaluation of liver function would be worthwhile if adequate tests were available. Blood cholesterol findings are relied upon by some but do not appear as satisfactory as the Quick hippuric acid test. Surprising evidence of liver impairment have been noted preoperatively in patients expecting an elective herniorrhaphy or interval appendectomy. Routine application of this test post-operatively as well as preoperatively would serve as an excellent index for the need of glucose which

is so valuable where liver function is diminished.

FRAZER, E. B. AND MEEKER, WM. R.

"Regional Ileitis — Clinical Report of Two Cases." *South. Med. Jour.*, 31:152, Feb., 1938.

Regional ileitis is probably a clinical rather than a pathological entity. Any portion of the small or large intestine may be involved but the lesion is most common in the ileum. The pathological process while resembling a new formation is neither neoplastic nor due to any specific organism. The involved segment is greatly thickened, heavy and reddened, the lumen of the bowel is irregularly distorted and narrowed, the mucosa is subjected to a destructive ulcerative edematous process, the submucosal and muscularis coats show inflammatory, hyperplastic and exudative changes, the mesentery is still and there are frequent adhesions to neighboring viscera with possible fistulous communication.

It is difficult to assemble the symptoms into a definite clinical syndrome. There is usually fever, diarrhea without tenesmus, loss of weight, progressive anemia, pain and ileocecal tenderness. The stools may be mushy or liquid and may contain mucus, pus, or blood. Vomiting, cramps, and constipation will depend upon degree of obstruction present. X-ray examination is of great aid. A characteristic finding is the beaded string appearance of the involved segment.

The pre-operative diagnosis is frequently incorrect. While cures have been reported following simple exploratory laparotomies surgical removal of the lesion seems to be the method of choice. (Note: Ileocolostomy with division of the ileum when no fistulae are present is not discussed by the authors).

Two interesting successful cases treated by resection of the ileocecal coil are reported.

RANKIN, FRED W. AND GRIMES, ALLEN E.

"The Surgical Treatment of Diverticulitis." *South. Surg.*, 7:1-15, Feb., 1938.

Diverticula occur in all portions of the gastro-intestinal tract from the esophagus to the rectum, but most frequently are found in the sigmoid colon. No adequate etiological explanation has been offered. It would seem, however, that from some unknown cause, probably congenital, a weakness exists in the intestinal coats and by reason of this a pouching of the coats takes place when any undue pressure arises. About five per cent of cases examined by barium enema will show diverticula,

DIET

When the impulse to defecate is lessened due to improper diet or lack of discipline, the fecal matter usually becomes dehydrated and impacted in the bowel. To simplify the problem of constipation, prescribe Petrolagar. It assists in the regulation of bowel movement. Petrolagar mixes intimately with the bulk of

the stool to induce a soft, easily passed mass. By reason of its pleasant taste and mild but thorough action, Petrolagar is agreeable to patients of all ages Five types of Petrolagar provide a choice of laxative medication suitable for the individual patient. Petrolagar Laboratories, Inc. • Chicago, Ill.

Petrolagar — Liquid petrolatum 65 cc. emulsified with 0.4 Gm. agar in a menstruum to make 100 cc.

Petrolagar

the vast majority of patients are beyond 40 years of age, and sex plays no part. The presence of diverticula causing no complaints is described as diverticulosis. With the onset of inflammatory changes the condition is designated as diverticulitis. Acute, subacute and chronic diverticulitis are considered to be fundamentally medical problems, and the complications of abscess formation, partial obstruction, massive hemorrhage, external or internal fistula, and associated malignancy essentially surgical.

Uncomplicated cases usually manifest themselves by some alteration in bowel habit frequently constipation alternating with occasional diarrhea. There is an associated variable degree of pain ranging from heaviness, fullness, or soreness to severe cramps; bleeding is rarely profuse and nausea, vomiting palpable mass, and stools of reduced caliber will be dependent upon the degree of obstruction present. Proctoscopic examination is often of great aid but the most accurate information is obtained from reliable roent-

genological studies. The principal findings are the rounded know-like projections from the lumen of the colon, spasm, and hypermotility. The relationship of cancer and diverticulitis is only coincidental and it must be remembered that diverticulitis with tumefaction may mimic cancer in its gross appearance. The diagnosis of the acute group perforating into the peritoneal cavity without abscess formation is quite difficult unless the previous presence of the diverticula is known. The condition is most frequently diagnosed as acute appendicitis or ruptured duodenal ulcer.

The type of surgical treatment indicated is determined by the nature of the complication requiring surgery. A single perforated diverticulum should be closed, drains packed around the involved area and a temporary colostomy done. Resection may be indicated in the perforating type which walls off, and forms an abscess which burrows to beneath the anterior abdominal wall, requires incision and establishes a fistula. Where obstruction is the main factor, where a large immobile mass is imbedded in the pelvis, a colostomy allowed to remain open for six to twelve months, during which time the Elliot treatment can be given, seems the best procedure to follow. If a vesicle fistula is present primary resection is not advisable. There should first be a colostomy and bladder treatments to clear up infection and inflammatory reaction.

Six illustrative cases are described.

J. Duffy Hancock, Louisville.

GAITHER, E. H. AND BORLAND, J. L.

Gastroscopic Studies. J. A. M. A., 110:436, Feb. 5, 1938.

The authors believe that reliable diagnosis in cases of gastritis can be made only on gastroscopic observations. History, roentgenograms, symptoms, and secretory studies have not proved sufficient. The impressions presented in this article are based on careful gastroscopic studies.

The normal gastric mucosa is unblemished, smooth, glistening, translucent and orange-red in color. In patients with dyspeptic symptoms or definite gastro-intestinal disease there are a wide variety of changes, apparently inflammatory in origin, but it has been impossible to establish criteria by which disease entities may invariably be recognized. The best working classification of gastritis is that of Schindler who divides it into three types, superficial, hypertrophic, and atrophic. In most gastritic stomachs the lesions seem active, the superficial and hypertrophic classes. In a small percentage the lesion seems atrophic and inactive.

The cases which show definite inflammation, a dusky red color, adherent patches of grayish mucous, areas of

*The Buffered
Neutral Antacid*

TRI-CALSATE

In the treatment of PEPTIC ULCER

... also hyperchlorhydria, heartburn and other conditions where the neutralization of gastric HCl is desirable, TRI-CALSATE has been found to be a powerful neutralizer—yet does not produce a harmful alkalosis.

It is in effect a "buffered neutral antacid" that eliminates the disadvantages of the alkaline antacids.

TRI-CALSATE is non-toxic and non-irritating. The probability of gastro-intestinal irritation is remote... the kidneys are unharmed. Patients like it because it is palatable and easy to take.

Available on Rx in 4 oz. and 18 oz. bottles.

redness, injection hemorrhage and superficial erosions the authors term superficial gastritis. If there are edematous rugae with hemorrhage or injection and the changes appear to be more than superficial but not actually proliferative or hypertrophic, the term "inflammatory" has been used.

In the hypertrophic cases the inflammation is not the predominant feature, the mucosa appears nearly normal in color but is thickened, the rugae are large but not edematous, small warty

nodules are seen between the folds, and there are small patches of mucosal thickening. Two other types have been recognized, that in which active inflammation is less evident but the entire stomach wall is involved in small hemorrhages and erosions and those in which there is a well marked granular appearance in the preantral zone, localized on the anterior wall.

Gastritis frequently accompanies gastric or duodenal ulcer, but the severity of the ulcer is no index of the

degree of gastritis. The superficial inflammatory type predominates. The two diseases may be considered as distinct.

In the atrophic group, the mucosa looks thin and unhealthy with a network of blue veins. The rugae are usually absent, and the color is bluish gray in some cases and has a yellow tinge in others. Often there is superimposed activity. These cases do not conform to previous clinical suppositions. They do not seem to follow atony, achylia, flaccidity or body type. The most marked evidence of atrophy is found in pernicious anemia.

Francis D. Murphy, Milwaukee.

WILBUR, D. L. AND WASHBURN, R. N.

Functional or Nervous Vomiting.

J. A. M. A., 110:477, Feb. 12, 1938.

The authors review 140 cases recently seen at the Mayo Clinic in which a diagnosis of functional vomiting was made. Many of these patients had previously undergone surgical procedures without relief. Of the 140 patients, 112 or 80 per cent were females and 28 or 20 per cent were males. Eighty-nine or 64 per cent were between the ages of 20 and 40 years. Seventy-five per cent of the patients vomited daily and the remainder had periods of remission. Vomiting occurred within one hour after meals in most cases and the immediate inciting causes were eating, nervousness, worry, excitement or emotional disturbances. These patients were frequently free of other gastro-intestinal symptoms. In this series, 51 or 36 per cent had some form of epigastric distress and approximately the same number suffered from constipation. The frequent vomiting did not seem to cause emaciation. Only 31 or 22 per cent of the patients were in poor general condition. The most common physical finding was some form of pelvic abnormality and in 104 cases the patient was of the "nervous" type. Other characteristic features were the ability of the patient to reach a receptacle before vomiting, the lack of abdominal symptoms, and the desire of the patient to eat again immediately. In many cases no abnormalities were revealed on examination, but there was a history of pelvic discomfort and dysmenorrhea.

Psychotherapy is the most important type of treatment. In some cases "treatment by explanation" is sufficient. In severe cases complete rest, restriction of food and fluids by mouth and sedatives may be necessary for a period of time. Ninety-seven cases were followed for at least two years and in 50 per cent of them the vomiting stopped completely, in 16.5 per cent the vomiting decreased or recurred and in 33 per cent no relief was obtained. The immediate prognosis is good and it has been found better for males than

DUOCHOL

(PLESSNER)

in the treatment of

Chronic Cholecystitis, Toxic Hepatitis, Stone-Free Cholangitis

Duochol exerts specific and dependable therapeutic influence upon the hepatobiliary mechanism. Its contained highly purified bile salts and sodium salicylate appreciably increase the rate of bile secretion and augment gallbladder evacuation. Drainage from both the larger bile ducts and the gallbladder is thus promoted, aiding in the removal of toxic accumulations and stagnant bile. Duochol produces prompt subjective relief and objective improvement in chronic cholecystitis, toxic hepatitis, and stone-free cholangitis.

Generous clinical samples of all Plessner bile products, together with literature, sent on request.

SPECIFIC MEDICATION

in specific biliary conditions

Plessner bile salt preparations present specific medication for specific lesions of the hepatobiliary tract.

TAUROCOL

(Plessner)

Tauocol is of unusual therapeutic value in mild chronic cholecystitis. Containing bile salts, stomachic, and laxative, it enhances biliary drainage and stimulates intestinal peristalsis.

TAUROCOL COMP.

(Plessner)

Contains pepsin and pancreatin in addition to the ingredients of Tauocol. Indicated when gastric or intestinal indigestion complicates gallbladder disease.

THE PAUL PLESSNER CO., DETROIT, MICH.

A Leader in Gastro-enterology Says . . .

"The recent advances in gastro-enterology have been of such magnitude and distinction that they engender in us a just pride and renew our determination to press forward toward our goal of perfection."

Dr. Ernest H. Gattner, Baltimore, Md., in his address at Kansas City before the section on gastro-enterology and proctology of the A.M.A.

The American Journal of Digestive Diseases

- Now in its fourth year of publication—without alteration in its fixed principle of giving to the reading members of the medical profession the contributions of the best clinicians and investigators in the United States, Canada and Europe.
- So formulated, and edited by one of the most capable and select editorial groups in contemporary medical journalism, the Journal has made unusual progress during the comparatively short period of publication . . . today, the editorial office is constantly in receipt of very valuable manuscripts which collectively form a cross section of new gastro-enterological thought.
- The absence of "politics" from this set-up ensures to the reader an unbiased preliminary evaluation of submitted material by men pre-eminently qualified to judge the worth of MSS in the various sub-fields of this broad specialty.
- Meeting the growing difficulty of prompt publication, the Journal is constantly diminishing its back log of material by insistence more and more, as time goes on, upon the idea of BREVITY in writing.
- The American Journal of DIGESTIVE DISEASES is not only making friends but it is KEEPING friends. The renewal percentage each year and each month is a positive proof of the sound, month-by-month value of the publication, and it is recognized that this Journal provides today, as no other publication ever provided, a trustworthy postgraduate education in a field much more intricate and fascinating than has been generally supposed.
- Once upon a time gastro-enterology was generally regarded as a specialty contaminated by faddism and quackery, but the pioneers, many of whom are still living and active on this editorial board have lifted it to the level of a strictly ethical study—and the Journal is playing an important role in facilitating this important branch of medical practice.

An Open Letter to the Physicians of North America

Do you realize that 60 per cent of all symptoms in general practice arise from the digestive tract?

Many diseases are intrinsic, and many at a distance reflect their symptomatology with great facility in the alimentary canal . . .

Is diagnosis of digestive diseases easy?

Apparently not. The old rule of thumb—"appendix, ulcer, or gall bladder" is no longer useful. We are becoming gradually acquainted with the disorders and diseases of the colon and reducing this information to some semblance of order. Physiology, bacteriology, chemistry, parasitology, clinical observation, animal experimentation, roentgenology, nutrition, allergy and psychology are the organized methods of approach to a fuller knowledge of

digestive diseases. And there still lies beyond, the dark continent of the small intestine, concerning which so little is positively known.

To the scholar, what is offered by this Journal is indispensable.

To the man too busy to indulge his yen for applied research, may we say this—an hour a month with the American Journal of DIGESTIVE DISEASES will provide the key to practical success in this most important, difficult, but "treatable" field.

Spend \$6.00 for a year or \$10.00 for 2 years NOW. Join the increasing group of doctors who enjoy this periodical. The card below is attached for your use, and is postage free.

B. COLI VACCINE

DETOXIFIED WITH SORICIN

FREQUENTLY obstinate cases of chronic toxic vertigo, chronic headache associated with colon distress and constipation, irritable colon and chronic functional diarrheas will respond to the combined use of Soricin Tablets and B. Coli Vaccine-Detoxified with Soricin.

SORICIN TABLETS

5 grain enteric coated tablets of sodium ricinoleate-Merrell supplied in bottles of 100.

B. COLI VACCINE DETOXIFIED with SORICIN

Prepared from selected strains of B. coli communis (Escherichia coli) and B. coli communior (Escherichia communior) mixed in equal proportions and detoxified with Soricin (sodium ricinoleate). For the convenience of the physician the individual treatment package, consisting of graduated dilutions ranging from 5 thousand organisms per cc. to 1000 million organisms per cc. has been made available.

Write for descriptive booklet "The Therapeutic Use of Soricin with Colon Bacillus Vaccine Therapy."

for females. The duration before treatment is not significant, but the more frequent the vomiting the less hopeful is the outlook for a permanent cure.

Francis D. Murphy, Milwaukee.

PAVEL, I.

Jaundice Caused by Functional Obstruction. J. A. M. A., 110:566, Feb. 19, 1938.

The pathogenesis of jaundice, except the hemolytic type and that due to mechanical obstruction, is uncertain. It has been supposed by some to be due to

hepatitis, but no decisive proof supports this view. The author has concluded that in a certain number of cases jaundice is caused by a reflex spasm of the sphincter of Oddi, a functional obstacle.

This type of case is characterized clinically by persisting icterus varying in intensity, unimpaired state of health, and discoloration of the feces. The positive diagnosis is based on examination of the biliary excretion by the Melzer-Lyon test. It is assumed in the present investigation that the spasm of

the sphincter of the common duct may be produced by pathologic changes situated in a region comprising the duodenum, the choledochus, and the head of the pancreas as well as changes in the pericholedochal lymphatics caused by regional inflammation including inflammation of the gall bladder.

Evidences of hepatitis were found in some of the author's cases. The important thing is to ascertain whether or not it has a part in the concomitant jaundice.

Functional obstruction explains many of the cases where symptoms of pain, fever, and jaundice recur after cholecystectomy. The disease termed idiopathic cyst of the common bile duct may also be explained by this spasm or hypertonia of the sphincter of Oddi.

The treatment of this type of jaundice varies with each case. Drainage by the Eihorn tube will usually suppress the jaundice, but not the underlying disease, and the icterus may return when drainage is stopped. Intermittent drainage over a long period of time is satisfactory in some cases. If medical treatment is unsatisfactory, surgical methods must be used to cause the bile to flow elsewhere than through the ampulla Vater. There is no danger in operating in such cases even if the jaundice is of long standing.

Francis D. Murphy, Milwaukee.

A PIONEER PRODUCT

HALEY'S
M-O

REG. U.S. PAT. OFF.

(The alkaline, mineral oil laxative)

Haley's M-O was the first preparation of this kind offered to the medical profession. It combines the gentle laxative and effective neutralizing properties of genuine Phillips' Milk of Magnesia with the lubricating action of mineral oil in a palatable emulsion.

No Irritation—No Leakage—Easy to Take

MOSENTHAL, H. O.

Pancreatitis and Diabetes. Ann. Int. Med., XI, 1001, Dec., 1937.

As an introductory the author makes a statement that the involvement of the pancreas as a cause for diabetes is to a large extent taken for granted. He thinks that the situation is quite similar as if all pulmonary conditions, such as tuberculosis, pneumonias, etc., were classified as a disease entity characterized by expectoration and treated alike on that basis. He calls attention to the well established fact that such pathological changes in the pancreas as carcinoma, cyst, adenoma, etc., are very well established, but that the lesions found in the pancreas in cases diagnosed clinically as diabetes mellitus are not satisfactorily evaluated. In his attempt to correlate the changes in the pancreas with the manifestations characteristic of diabetes, he adjures the reader that the conclusions reached are but tentative and that further laboratory, as well as clinical data, must be had.

While diabetes is caused by an involvement of a majority of the islands of Langerhans, attention is called to the fact that a pancreatitis that results from such lesions may be permanent or transient and that it may be chronic or acute. He thinks that chronic pancreatitis that develops in elderly people as a result of arteriosclerosis and other senile changes should really be

Useful... IN MANY INVALID AND CONVALESCENT DIETS

RIPE BANANAS are a natural, soft, bland food... with a delicate flavor... popular with most persons... nourishing... easily digested... mildly laxative... non-irritating... do not readily ferment in the intestines... create intestinal conditions unfavorable to the growth of putrefactive bacteria... yield alkaline mineral residues in the body.

Because of these attributes, together with their soft fibre, pectins, high content of sugars, satiety value, low content of protein and fat, their vitamins (good source of A-B-C-G) and essential minerals, ripe bananas are prescribed by an increasing number of physicians in many invalid diets, including: ulcerative colitis; peptic ulcer; cardiac; diabetes; liver disorders; nephritis; tuberculosis; as well as in various post-operative and convalescent diets.

In the field of corrective diets, physicians are finding that ripe bananas help combat both diarrhea and spastic constipation; also that in combination with milk they constitute a basis for planning a variety of effective, safe reducing diets for persons who are overweight.

LITERATURE ON REQUEST... ADDRESS

UNITED FRUIT COMPANY *Educational Dept., Boston, Massachusetts*

classified as a primary chronic pancreatitis, that this form of pancreatitis is a slowly progressive change that occurs in late middle life or old age and may be generally recognized as the essential diabetes of Naunyn and rests primarily from a causative factor at a point upon the degenerative changes that are incident to advancing years. He sharply distinguishes this form from those forms of diabetes that are found in younger people that are characterized by periods of exacerbation and remission.

Hyalinization of the islands occurs almost entirely in persons over 40 years

of age, but it may be also found in non-diabetics. Fibrosis is more frequent in older individuals and yet it is not often mentioned as a cause for diabetes. Fibrosis and hyalinization of the islands may be found in the same pancreas, in fact, the two lesions may even be combined in the same island.

When a chronic pancreatitis is the sequel of scarring, resulting from an acute pancreatitis or from pancreatic duct obstruction, it should be considered as a secondary chronic pancreatitis in contradistinction to the above chronic form which is called the primary chronic type. In the secondary

type of chronic pancreatitis the destruction of cell tissue is brought about through pancreatic calculi or external pressure or acute pancreatitis, by pancreatic cysts or by hemorrhage within the tissue of the gland. The subsequent development of the diabetes depends entirely upon the number of islands which are destroyed. If only a few are killed, clinical diagnosis does not result. The diabetes from the secondary type of chronic pancreatitis is usually mild and generally non-progressive.

Classification of Fitz, designating the varieties of acute pancreatitis as hemorrhagic, gangrenous and suppurative, is followed, though attention is invited to the thought that they should be considered as parts of the same process, namely, acute pancreatitis. Pratt is quoted as stating that these forms of acute pancreatitis "represent different stages in the same pathological process that begins with necrosis of the pancreas." Gall bladder disease, edema and hemorrhage of the pancreatic parenchyma are mentioned as causes of acute pancreatitis.

Clinical manifestations are considered under three headings and this classification holds good whether the cause be chronic or acute pancreatitis.

1. Carbohydrate metabolism. This is interfered with to a very mild degree and there is only a tendency to a very slow progress in the chronic type due to arteriosclerosis, whereas in younger individuals the interference with carbohydrate metabolism is much more marked, though it must be recognized that an acute pancreatitis may or may not be accompanied by hyperglycemia and glycosuria. Likewise it may cause the transient appearance of diabetes which will subsequently clear up.

2. Fat metabolism. While the oxidation of fat is associated with carbohydrate metabolism, yet it must be remembered that the oxidation of fat does not depend entirely upon the utilization of glucose but only that the oxidation of B-oxybutyric acid is contingent upon the carbohydrate metabolism. Other agencies determine the change of a fatty acid in a chain of 16 or 18 carbon atoms to the 4 carbon chain of B-oxybutyric acid. It is an excess of this latter fatty acid that results in diabetic acidosis.

The oxidation of fats up to the B-oxybutyric acid stage, while not influenced by the islands of Langerhans, is a pancreatic function. The evidences of a disturbed fat metabolism in the diabetic are hypercholesterinemia, lipemia, xanthoma and a fatty liver and spleen. A hypercholesterinemia may occur in a mild diabetic with a well controlled carbohydrate metabolism and without acidosis. It may be taken as an index to the degree of lipemia. There seems to be a dissociation of fat and carbohydrate metabolism in these cases. A hyperglycemia, glycosuria,

IN PEPTIC ULCER

ROENTGENOLOGICALLY DEMONSTRABLE

Healing

IN SEVEN TO TEN DAYS

When administered continuously by the Creamalin Automatic Drip Control, Creamalin leads to skiagraphically discernible healing in 7 to 10 days. Since a state of anacidity is constantly maintained within the stomach, all pain disappears with the institution of therapy. The patient is subjected to virtually no discomfort, and is permitted to enjoy a sustaining diet. All types of peptic ulcer, including those associated with marked pylorospasm, as well as actively bleeding lesions, respond to this therapeutic procedure.

Creamalin
REVOLUTIONIZES ULCER THERAPY

Many physicians today are recommending a diet fortified with protective foods for underweight children. Diets believed to be adequate are often deficient in some important respect.

Lack of appetite is often one of the early manifestations of a defective diet. Correction of the defect may quickly show an improvement in appetite.

Faulty nutrition is a common cause of underweight in children. The addition of Ovaltine to the usual diet intrigues the taste as extra values are added.

Anorexia, Failure to Gain in Weight...

and Corollary Problems may be due to Deficiencies in Diet

Symptoms of mild, subclinical dietary deficiencies in children are fairly common even among "well-fed" groups. Diets thought to be adequate, many times are deficient or lacking in some essential factor.

Many physicians today are finding that fortifying the diet with protective foods often brings beneficial results. More and more, they are turning to Ovaltine as a food supplement. For Ovaltine supplies valuable protective food elements in a delicious liquid form.

Ovaltine contains a variety of protective food factors. It supplies vitamins A, B₁, B₂ and D, and the minerals calcium, phosphorus, copper and iron. (See table.)

Not only does Ovaltine increase the consumption of milk, but it makes milk a more digestible, more palatable and more valuable food. For example, Ovaltine provides 120

U.S.P. units of vitamin D in each serving, a factor in which ordinary milk is frequently low.

Best of all, Ovaltine is economical. A single serving for only 2½ cents is a remarkably low cost for such high food value.

Try Ovaltine with your child patients who are underweight. It is a pleasant and valuable method of fortifying the diet that children will quickly approve.

OVALTINE CONTAINS THESE PROTECTIVE FOOD ELEMENTS:

Vitamin A	Calcium
Vitamin B ₁	Phosphorus
Vitamin B ₂	Copper
Vitamin D	Iron

acidosis, xanthoma and lipemia obtaining in a patient may have the blood sugar reduced to normal and the acidosis cleared up while the lipemia lags. This would appear to argue that the appearance of these products of disturbed metabolism are brought about by a suppression of a different pancreatic function. Acidosis without lipemia is common; lipemia in the absence of glycosuria likewise occurs. If the thesis of an independent control of fat and carbohydrate metabolism by the pancreas is correct, the author argues that the hormone discovered by Dragstedt and his associates, called "lipocaine" may prove the solution of a disturbance in fat metabolism through the pancreas, apart from that regulating the carbohydrate metabolism. This new substance must await clinical trial.

3. Blockage of the pancreatic ducts. This is characterized by "pancreatic stools"; they are yellow, malodorous, bulky, and there is an absence of pancreatic ferments. Evidence of carbohydrate metabolism may or may not become manifest, but whether diabetes is or is not present, the relief from the "pancreatic stools" can be secured by the administration of raw pancreas only.

The author concludes that the pancreas is the organ which, when diseased, is responsible for the disturbed carbohydrate metabolism; that chronic pancreatitis is the result of senescent processes; that acute pancreatitis, in a mild form, may be a cause of the difficult onsets of diabetes in young patients; that pancreatitis results in (a) interference with carbohydrate metabolism; (b) disturbance of the fat metabolism and (c) that an occlusion of the pancreatic ducts with lack or loss of the external secretion of the pancreas in the intestine which in turn results in "pancreatic stools."

Virgil E. Simpson, Louisville.

DRAGSTEDT, L. R.

Lipocaine, Northwest Medicine, 37: 51-56, Feb., 1938.

As a result of animal experiments the author concludes that there is present in fresh pancreas and probably in the islet tissue a specific substance, apart from insulin, which plays a role in the transport or utilization of fat. It is not present in the external secretion so it is probably an internal secretion or hormone for which the name "lipocaine" has been chosen. Without this hormone the denaccretized dog almost inevitably dies within a few months in spite of most careful dietary regulation and insulin administration, whereas with it and insulin the same animal may survive in excellent condition for several years. The substance was found to be present in the fat-free part of a 60 per cent alcohol extract of the fresh tissue.

The author calls attention to the

possibility that diabetics suffer from a lipocaine deficiency as well as an insulin deficiency, and that this manifests itself in a disturbance in fat utilization with the deposition of fat in the liver and in more chronic cases in the sub-endothelial layers of the arteries.

Hanes M. Fowler, Fort Wayne.

GUSTAFSON, EINAR G.

An Analysis of Sixty-two Cases of Primary Carcinoma of the Liver, Based on 24,400 Necropsies at Bellevue Hospital, Ann. Int. Med., XI, 882, Dec., 1937.

The autopsies from which the cases reported in this study were taken were 24,400 consecutive autopsy studies that had been made at the Bellevue Hospital in a period of thirty years from 1906 to 1936. The 62 cases that were selected for review were all primary carcinomas of the liver. 53 of the cases selected were males and 9 females. The average duration of the time when the history began until death was 3.2 months. Considered from the standpoint of cell type, it was noted that the average course of the liver cell type was 2.5 months, while that of the bile duct type was 4.1 months. From a pathological viewpoint it was found that 25 of the 39 cases of the liver cell type, or 64.1 per cent, were attended

Crystalline VITAMIN C

Crystalline Vitamin C

- In Enforced Dietary Restriction
- Gastro-Intestinal Disease

Patients with necessary dietary restrictions, such as exist in the Sippy, ketogenic, and certain other diets of insufficient vitamin C content, constitute an important group in which the use of vitamin C in concentrated form may be of value.

Stringent adherence to fruit-free diets in the protracted treatment of peptic ulcer, colitis, urticaria,

and other conditions may result in mild or even frank scurvy, unless care is exercised to ensure an adequate intake of vitamin C.

In the presence of gastro-intestinal disease, impaired absorption may cause vitamin C deficiency despite a presumably adequate intake of the vitamin.

When there is persistent vomiting, diarrhea, or any other condition preventing the utilization of an adequate amount of vitamin C, the parenteral administration of Cebione will be of value.

OLEUM PERGOMORPHUM CAPSULES

for diets deficient in
VITAMINS A and D

Where there is an intolerance or an aversion to fats, such good sources of vitamin A as dairy products are studiously avoided by patients. Obesity, diabetic, pregnancy, and low-cholesterol diets especially tend to be deficient in vitamin A. Oleum Pergomorphum Capsules offer a convenient and highly acceptable means of correcting this deficiency and also furnishing generous amounts of vitamin D. Each 10-drop capsule supplies not less than 13,300 A units and 1,850 D units (U.S.P.), the equivalent of more than 5 teaspoons of U.S.P. cod liver oil in natural vitamins.

MEAD JOHNSON & COMPANY
Evansville, Ind. U. S. A.

with some degree of cirrhosis, while only 3.3 per cent of the bile duct cell type showed detectable cirrhosis. In the microscopic study of tissues attention is called to the necessity of examining uninvolved tissue to exclude factors of error. For example, biliary obstruction due to tumor, encroachment on biliary ducts, will lead to fibrosis of liver tissue, yet this fibrosis is biliary in origin rather than portal. Only two cases of the series were of the dual or indeterminate type of cell structure. The study of metastases in the group brought out the following features. Solitary distinct metastases as to brain, bone, kidney, etc., were not uncommon. In 19 cases, or 30.6 per cent, even naked eye evidence of neoplastic venous thrombosis was present. In six of the 19 cases there were visceral metastases likewise visible to the naked eye. In two cases tumor thrombi were found to have travelled through the inferior vena cava to the right auricle of the heart. In several the splenic vein was thrombosed throughout its entire length. In 29 cases, or 46.8 per cent, there were no naked eye evidences of metastasis. In the remaining 33 cases the sites of metastases were numerous, more frequently in the periportal lymph nodes and the lungs, particularly the right lung. Only 3 cases of metastasis to bone were found. One of these was found in the ribs, vertebral and left orbital bone. In the other two the ribs only were involved.

Reference to the size of the liver was made and in 48 cases the liver had been weighed. The average was 2900 grams. There was very little difference in the size of the liver in the liver cell type of neoplasia and in the bile duct type. Ascites was present in 72.6 per cent and was found to be the most constant approximate in the series. The ascites was bloody in six and sero-sanguineous in seven others. An enlarged spleen was found in a majority of cases. The average was 351 grams and was slightly higher in the bile duct type of tumor. Jaundice was infrequent in neoplasia of the massive type. This was explained on the basis of biliary obstruction by pressure from tumor nodules, and in tumors of the massive type secondary nodules were infrequent.

Only seven of the whole 62 cases of the series were diagnosed clinically. One had been diagnosed as carcinoma of the stomach with metastasis to the liver. Another had been diagnosed as cirrhosis of the liver, another as carcinoma of the head of the pancreas, and another as malignancy of the liver with the primary site undetermined, and another of cardiac decompensation. In the remaining 55 no available data was found in their study to show that the possibility of primary carcinoma of the liver was even suggested.

Reference is made to the criteria which Symmers in correlating his

Ulcer Therapy *Simplified*

STANDARD REGIMEN

In the standard Sippy procedure, milk and cream mixtures are fed on the hour, alkali on the half-hour. The many feedings—usually 29 daily—are a major disadvantage.

SIMPLIFIED PROCEDURE

Add alkali to KLIM and feed hourly.

More efficient control of gastric acidity, with only 14 daily feedings, is reported* for this procedure. Reason: 27% higher protein content—and the finely divided KLIM curd, which presents a very much greater combining surface to the stomach acid.

TRY KLIM in your next ulcer case. Simpler, more convenient, more effective. Patients will tell you, too, that KLIM is more economical. Vacuum-sealed and gas-packed, KLIM is available, always fresh, in almost any drug store. *Stays fresh* for weeks after the tin is opened. Send coupon to receive trial supply and further information on KLIM.

twenty years experience in the necropsy room and wards of Bellevue Hospital had set up. These criteria were:

- (1) A male patient over thirty-five years of age.
- (2) A large palpable tumor mass in the right lobe of the liver.
- (3) No primary tumor discoverable elsewhere.
- (4) Jaundice, usually mild.
- (5) Ascites.
- (6) An otherwise unexplained fever of mild degree.

As a consequence of this study the following conclusions were drawn:

1. Primary carcinoma of the liver occurred once in every 324 necropsies at the Bellevue Hospital in the thirty years covered by the study. This represented an incidence of 0.25 per cent on the 24,400 necropsies.
2. Primary carcinoma of the liver is a clinical and pathological entity susceptible of diagnosis during life.
3. The clinical diagnosis may be postulated with reasonable certainty on the criteria set up by Symmers.
4. Cirrhosis was found in 51.6 per cent in association with the tumor and in six cases hemochromatosis of the liver was found in conjunction with cirrhosis.
5. The bile duct type of tumor is histologically indistinguishable from the duct cell carcinoma of the pancreas.

CASTLE, W. B., HEATH, CLARK, W., STRAUSS, MAURICE B. AND HEINLE, ROBERT W.

Observations on the Etiologic Relationship of Achylia Gastrica to Pernicious Anemia. (From the Thorn-

dike Memorial Laboratory, Boston City Hospital and Harvard Medical School). Am. Jour. Med. Sciences, p. 618, Nov., 1937.

It is assumed "that the effective principle in the liver of the normal person is in some way formed from the interaction of food and gastric factors. The problem as to how and where in the body such a transformation occurs remains, however, quite unsolved." "Normal human gastric juice freed by absorption methods of both pepsin and rennin still contains intrinsic factor." "Administration of beef muscle and gastric juice, separately at an interval of 6 hours results in increased blood production." This the authors say "eliminates the necessity of hypotheacating an in vitro phase for the production of the activity of incubated mixtures." When the administration of beef muscle and gastric juice are separated by an interval of 12 hours or more there is a negative effect upon blood production. "Neutral mixtures of gastric juice and beef muscle are effective when administered to the achylic pernicious anemina patient. Therefore, so far as the reaction is concerned a suitable environment might be found as well after absorption within the body as before leaving the alimentary tract." The authors found that "Mixtures of beef muscle and gastric juice administered at pH 1.8 to 2.5 are ineffective." If, however, such incubated mixtures were given at pH 5 or pH 7 a positive effect on blood production appeared.

"Whether failure of the acid digest to cause increased blood production was due to the destruction of the extrinsic or intrinsic factors before effective interaction could occur or whether it was due to such acidity that interaction could not take place was the basis of further analysis." As it was found that incubation of the beef muscle and gastric juice mixture at pH 1.8 or 2.5 for 6 hours did not abolish its activity if it was brought to pH 5 or 7 before administration; if the mixture was not so neutralized it could be argued that after it was given to the patient continued in vivo incubation of the acid mixture was responsible for failure through subsequent destruction of the intrinsic factor. This question was put to test and the authors found it probable that "the negative effect of administration of incubated mixtures of beef muscle and gastric juice at an acid reaction, was not due to a prolongation of any destructive action of the acid medium on the extrinsic or intrinsic factors after administration to the patient." The writers found that "temperatures without significant destructive effect on aqueous solutions of an unpurified liver extract abolish the activity of mixtures of beef muscle and gastric juice after incubation for 2 hours at pH 7." In addition they found that "temperatures without significant destructive effect on aqueous solutions of liver extract abolish the activity of mixtures of beef muscle with normal human duodenal contents or with hog duodenal and small intestinal mucosa after incubation for 2 hours at pH 7." They further state that "the destructive effect of temperature on the mixture given these patients was not on the extrinsic factor in the beef muscle is clear. Mixtures of gastric juice with a 48 hour peptic digest of beef muscle previously boiled for 5 minutes with autoclaved, autolyzed yeast or with hog stomach mucosa which has been boiled for 2 hours, are hematopoietically effective."

Allen Jones, Buffalo.

EINHORN BUCKETLESS GASTRO-DUODENAL TUBE

As Designed by Dr. Moses Einhorn, New York City

The Einhorn Tube illustrated combines in its new principle all the advantages of other tubes. In addition, the following superiorities are self evident.

- Weighted tip encased in tube.
- No possibility of tip becoming detached.
- Easier to swallow because pear shaped.
- No rough edge of knot between tip and tube to irritate mucous membrane.
- Eliminates fear of patient which is apparent when metal tip is swallowed.
- Pear shaped weight distributed so that lower part is 3 times heavier than upper part—total weight 150 grains.
- Weight distribution keeps tip in its proper place in progress through the pyloric opening.
- Lumen between weight and first eye filled so will not accumulate food.
- No likelihood of regurgitation from the duodenum.
- Weight distribution of lip anchors tube in the duodenum.
- No discomfort at plottis on removal—gradual taper shape makes removal easy.
- No possibility of cutting mucous membrane in suction.
- Slotted oval opening—offers large drainage area and prevents clogging of tube.
- Will not adhere to visceral wall—Arc is formed by tip and tube which keeps openings away from wall.

Size 14 French, length 10". Flexible red rubber, semi-soft and resilient, 2 slotted oval eyes. Markings at 12", 24" and 32" from tip.

Burton, Parsons & Co.

(Established 1885)

Washington, D. C.

Decholin has the above formula. It is available in 3 $\frac{3}{4}$ gr. tablets for oral administration, and in the form of its sodium salt for intravenous injection in ampules of 5% and 20% solution when intense and rapid choleresis is indicated.

For Prompt, Intense Choleresis...

DECHOLIN-SODIUM

For Maintenance Thereafter...

DECHOLIN TABLETS

In hepatobiliary infections when especially rapid and intense increase of bile secretion is desired, the combined use of Decholin tablets (chemically pure dehydrocholic acid in crystalline form) and Decholin sodium is recommended. One or two intravenous injections of Decholin sodium soon promote the desired intensified bile secretion; thereafter, the oral administration of Decholin tablets helps to maintain it.

The increased flow of thin liver bile aids in the disposal of inspissated secretions within the bile ducts and facilitates intrahepatic as well as extrahepatic drainage.

Decholin and Decholin sodium are of established value in chronic cholecystitis, noncalculous cholangitis, hepatitis of toxic origin, biliary insufficiency, biliary engorgement, and before and after biliary tract surgery. Contraindicated only in complete obstruction of the hepatic or the common bile duct.

Comprehensive literature, and the second edition of the brochure "Biliary Tract Disturbances" available to the profession on request.

BASIC OPERATIONS IN COMMERCIAL CANNING PROCEDURES

II. THE BLANCH

● Previously, we have described the reasons for the thorough cleansing of raw food materials prior to canning and the methods by which such cleaning is effected. Another basic operation in the commercial canning procedures for many vegetables and some fruits, is known as the "blanch". (1)

In essence, the blanch is an operation in which raw food material is immersed in warm or hot water, or exposed to live steam. The blanch serves a multiple purpose.

First, blanching serves to soften fibrous plant tissue. By so doing, it contracts or expands these tissues and thus insures a proper final fill in the tin container. Second, during the blanch, respiratory gases contained in the plant cells are liberated. This release of gas prevents strain on the can during heat-processing and favors development of a higher vacuum in the finished product.

Third, the blanching operation inhibits

enzymes naturally present in the raw foods and prevents further enzymatic action. Inhibition of enzymes—particularly those inducing oxidative reactions, yields products of superior quality and nutritive values. Fourth, the blanch may serve as an added cleansing measure and also remove "raw" flavors from certain foods. A final function of the blanching operation is to fix or set the natural color of specific products.

In commercial canning practice, blanching is usually accomplished in equipment especially designed for certain types of products. In general, the raw products after thorough washing are conveyed through water or steam by various mechanical devices capable of adjustment so as to subject the raw materials to a particular temperature for the proper period of time.

Such, in broad detail, are the purposes and mechanics of the blanch, a basic operation in many commercial canning procedures.

Synopsis of DIGESTIVE DISEASES

By JOHN L. KANTOR, Associate in
Medicine, Columbia University.

302 pages, 40 illustrations. Price
\$3.50.

This book presents simply, clearly, and concisely, the essential facts concerning the diseases of digestion. An effort has been made to preserve the proper balance between stress and subordination, inclusion and omission; and to emphasize throughout, the ways in which gastroenterology fits into the larger field of internal medicine. To this end the opening chapter on classification has been designed for early orientation, clinical syndromes common to many diseases have been elaborated as fully as possible, and a final section has been devoted to digestion symptoms in extradigestive diseases.

OUTSTANDINGLY DIFFERENT

Because . . .

- 1st. It Covers ALL Methods of Treatment—Drugs, Diet, Hydrotherapy, Physiotherapy, Psychotherapy, etc.
- 2nd. Therapeutic procedures are so plainly described and illustrated that any one can follow through successfully the procedures recommended.
- 3rd. It is an Individual Text. It is not a Mere Citation of the Work of Others, but Clendenning at his Best.
- 4th. It is Inspirational, Instructive, Up to Date (Published, October, 1937), and Based on Last Edition of the U. S. P.

CRITICS APPROVE

ARCHIVES OF INTERNAL MEDICINE says:

"This book still remains the classic in the field of medical treatment for the practitioner and student. The lucid manner in which it is written and the fact that it includes every important field in medical therapeutics makes it a necessary addition to any medical library."

THE JOURNAL OF THE A. M. A. says:

"The book is, in every sense of the word, an individual textbook of therapy, reflecting its author's personality. . . . This is a textbook of therapeutics that is readable, sounder than most, and certain to be useful. . . ."

Amebic Dysentery in North Carolina

By

JULIAN M. RUFFIN, M.D.*
DURHAM, NORTH CAROLINA

FOR many years amebic dysentery has been regarded as a tropical or subtropical disease (1). The recent epidemic in Chicago (2) tended somewhat to discredit this belief, but so firmly is its tropical nature fixed in the minds of the profession that the disastrous consequences of that outbreak may soon be forgotten, or at least, it will no longer occur to many of us who live in the temperate zone that the cause of our patients' illness may be an amebic infection.

The purpose of this communication is to emphasize the prevalence of the disease; to show how easily the diagnosis can be made; to point out the gratifying results which almost invariably follow adequate treatment; and to warn the profession of the tragedy which frequently overtakes the improperly treated or neglected patient.

Material: This report is based upon a group of 54 patients with proven amebic infection who have been studied in Duke Hospital during the past six years. The distribution according to race and sex is shown in Table I.

TABLE I

	Male		Female		Total
	White	Colored	White	Colored	
Number	41	5	6	2	54
Percentage	76	10	11	3	100

All ages were affected; the youngest patient in this group being two years, the oldest being sixty-six years of age. The distribution by decades is shown in Table II.

TABLE II

	0-9	10-19	20-29	30-39	40-49	50-59	60-69
Number	3	3	9	14	9	11	5
Percentage	5.5	5.5	17	26	17	20	9

With the exception of one patient whose infection could be traced to the Chicago epidemic, and of three patients who lived in border counties in South Carolina, all the patients in this series were residing in North Carolina at the time of onset of the disease. The distribution throughout the State is shown in Fig. 1. The duration of the disease could not be accurately

determined in some instances, but varied from a few weeks to several years and many gave a history of one or more relapses.

DIAGNOSIS

The diagnosis was established in 46 of the 54 patients by demonstrating the active, motile forms of *Endameba histolytica* in the stool or in the material obtained by proctoscopic examination. Because of the difficulty of identification and of their doubtful significance, the presence of cysts in the stool was not accepted as sufficient evidence of the disease, though indicating a carrier state. In six patients the diagnosis was made at autopsy, and in two patients with liver abscess, typical ulcers were observed by proctoscopic examination, though no amebae were demonstrated. However, the prompt subsidence of symptoms following treatment was thought to justify the diagnosis of amebic infection in these two patients.

STOOL EXAMINATION

Repeated examination of the stools was made in 44 cases. This was positive in only 24 patients (or 55%).

PROCTOSCOPIC EXAMINATION

Proctoscopic examination was performed in 35 patients. Typical punched out ulcers with normal intervening mucosa were observed in 31 of these patients (88%). In one patient with a liver abscess the mucosa was entirely normal, and in the remaining three patients the proctoscopic picture was suggestive of an extensive non-specific ulcerative colitis, yet amebae were demonstrated in smears. Smears obtained by proctoscopic examination were positive in 32 patients (91%).

BARIUM ENEMA

X-ray examination of the colon by barium enema was made in 19 cases. In 6 of these (32%), the colon was reported entirely normal. In the remaining 13 patients, the portions of the colon which were reported as exhibiting evidence of infection are shown in Table III.

TABLE III

	Cecum	Asc.	Trans.	Desc.	Sigmoid	Rectum
Number	5	5	4	9	10	5
Percentage	28	35	31	70	77	35

In no case could the diagnosis of amebic dysentery be definitely established from the X-ray findings alone.

COMPLICATIONS

Six patients in this series had liver or lung abscesses. One liver abscess was drained surgically with complete recovery. Three were treated with emetine, with

*Department of Medicine, Duke University School of Medicine.
Submitted October 22, 1937.

gradual subsidence of symptoms, and were discharged as cured. In two patients the abscess ruptured into the pleural cavity and the diagnosis was made at autopsy. Neither of these received specific treatment. One other patient had a pelvic abscess, and another a generalized peritonitis from a perforated colonic ulcer. Both of these patients were moribund on admission and died shortly thereafter.

TREATMENT

There were 35 patients with frank, uncomplicated amebic dysentery who were treated intensively with carbarsone, yatren, or emetine, or combination of these three drugs, as shown in Table IV.

TABLE IV

	Carbar- sone	Yatren	Emetine	Carbar- sone and Yatren	Emetine and Yatren
No. of patients	10	8	5	11	1
No. days before subsidence of diarrhea	3-4	3-4	4-5	2-3	3-4

The doses used were: carbarsone 0.25 Gm. twice daily for ten days orally; yatren 5 Gm. in 250 c.c. of water as a retention enema daily for 7-10 days, and emetine hydrochloride 0.1 Gm. subcutaneously daily for 7-10 days.

In a great majority of these patients a marked change in their general well being was noted twenty-four to forty-eight hours after starting the treatment, and the diarrhea was checked by the third or fourth day. The best results were obtained with the use of carbarsone by mouth in combination with yatren as a retention enema. In 18 patients the appearance of the

cating disease was unaffected. Anderson, Delprat, Weeks and Reed report a similar experience (3).

RELAPSE (FOLLOW UP)

Information in regard to the condition of the patient since leaving the hospital was obtained in 22 patients. In 6 of these there had been a definite relapse which promptly subsided after another course of treatment. There was no relationship between the relapse and the drug which had been used.

DEATHS

There were seven deaths in this series, a mortality of 13%. Six of these patients came to autopsy. Two had liver abscesses which had ruptured into the pleural cavity. One had a general peritonitis from a perforated ulcer. Three had extensive involvement of the colon but had received no treatment, and the patient, on whom there was no autopsy, had a pelvic abscess.

DISCUSSION

Several points of interest are brought to light by this study. Of greatest importance is the prevalence of the disease in a state whose climate is far from tropical. That the disease is endemic and widely scattered over the state is shown by Fig. 1. Amebic dysentery is not reportable in North Carolina, consequently this group certainly represents only a fraction of the total number of patients. It is possibly of some significance that very few patients came from the western part of the state which is largely rolling or mountainous country.

The importance of proctoscopic study is shown by the fact that stool examinations were positive in only 55% of the cases, whereas, the smears taken from the ulcers were positive in 91%. The appearance of the ulcers seen on proctoscopic examination is so characteristic as to be diagnostic. Occasionally, there is extensive ulceration which is confusing and the examiner must decide between a chronic ulcerative colitis and severe amebic ulceration with secondary infection. In such cases the therapeutic test must be

Fig. 1. Distribution of cases in amebic dysentery.

rectal mucosa was observed by proctoscopic examination after treatment. Evidence of healing was noted as early as the fifth day, and by the tenth day all traces of the ulcers usually had disappeared. In 5 patients, a mixed infection was present (ulcerative colitis in four cases, and typhoid fever in one). These patients showed very little improvement under treatment. The amebae disappeared from their stools, but the compli-

resorted to. It is a fairly safe rule that any diarrhea which fails to respond to adequate specific treatment is not due to amebic dysentery.

While it is generally accepted that the cecum is the site of predilection in amebic infection (4), in this series ulcers could be demonstrated by proctoscopic study in 31 out of 35 patients (88%); and in 5 patients coming to postmortem, ulcers were present

not only in the cecum but also in the rectum. In the sixth patient, the rectum and sigmoid were normal, the ulcers being confined to the cecum and ascending colon. X-ray studies likewise confirmed the impression that the descending colon, sigmoid and rectum were much more frequently involved than formerly had been thought.

Complications are all too frequent and usually serious if not fatal (5, 6, 7, 8, 9). In this series there were 8 patients, or 15%, with complications such as liver or lung abscess, or peritonitis from a perforation.

It is of interest to note that in three patients, the infection developed shortly after operative procedure—one after an appendectomy, one after a hernia repair, and one after prostatic resection. It is suggested

that these patients were carriers and the operation precipitated the active disease.

Finally, the gratifying results (10, 11) which almost invariably follow adequate treatment should be emphasized. Patients who have been ill for months or years are relieved of their symptoms within two to three days. In this series no deaths occurred in patients who had received adequate treatment.

CONCLUSIONS

1. Amebic dysentery is prevalent in North Carolina.
2. Diagnosis is relatively easy, if proctoscopic examination is employed.
3. Adequate treatment is highly effective.

The Proctological Aspects of Diarrhea*

By

GARNET W. AULT, M.D.†
WASHINGTON, D. C.

INTRODUCTION

THE proctological significance of diarrhea is attaining increasing importance as an aid in the diagnosis of many disorders classified under the inaccurate term "colitis." In the light of our present knowledge, one is not justified in assuming that a gastro-intestinal investigation is complete unless a proctosigmoidoscopic examination has been made. This direct visual examination of the anus, rectum, and pelvic colon has no substitute, and it should be the harmonious accompaniment of the barium enema and other indirect methods of investigation. We are all, including the roentgenologist, aware of some of the inherent difficulties experienced in demonstrating some of the ulcerative and early malignant lesions of the rectum and pelvic colon and it is in this type of case that direct visual examination of the accessible portion of the bowel is clearly indicated.

All cases of diarrhea demanding or requiring thorough investigation should have a detailed history and general physical examination. Competent laboratory examination of the stools for parasites and ova, bacteriological studies of the stool and of cultures and scrapings obtained during sigmoidoscopy should be evaluated. Gastric analysis and cholecystograms may be indicated. Special hematological studies, basal metabolism and skin tests should be done when indicated.

If we are all able to completely investigate a cooperative patient and make a correct diagnosis there should be very little excuse for the existence of the food faddist, the quack, or the charlatan. Patients who sometimes consult such really belong to the clientele of the ethical internist and gastro-enterologist, and both of these physicians should consider the endoscopic visualization of the anus, rectum, and pelvic colon as a part of their diagnostic armamentarium. One should be aware that proper interpretation of findings is essential to this examination. Gentleness and ease of examination should be developed, and lest anyone is not aware of some of the dangers, they are respectfully referred to Crohn's article "Trauma Resulting from Sigmoid Manipulation" (1).

Diarrhea, as induced by some of the more common disorders, is discussed from a proctological standpoint.

ACUTE DIARRHEA

Contrary to popular opinion, the individual who conducts a proctoscopic examination upon a patient in the throes of an acute diarrhea, is neither a hero nor a fool. In the absence of an inverting type of table, it is possible to conduct such an examination in the home, hospital, or office by inverting the patient over the edge of the bed or the examining table. A pillow placed on the floor, upon which the head and elbows may be rested, can be used. Liquid stool will thus not be forced out of the instrument. I might also state that the instrument with the proximal light is handled

*From the Department of Proctology, Georgetown University School of Medicine.

†Professor of Proctology, Georgetown University School of Medicine. Submitted July 23, 1937.

with greater ease in these cases than one with the distal light. The continual soiling of the distal light, or its "window," may prevent adequate examination.

In preparation for examination, the patient is requested to take a plain water enema one to two hours before examination. It is to be noted at this time that a mistaken interpretation of "injection and inflammation of the mucosa" has often been made following the administration of a medicated enema, notably of the strong soap suds variety. Excessive purgation, especially with the saline group of cathartics and the strong vegetable compounds, may induce a low grade inflammatory change in the lower bowel. Adequate cleansing with plain water—until the return flow is clear—represents the ideal preparation for proctosigmoidoscopic examination.

In the presence of an active acute diarrhea, as previously mentioned, what should one expect to encounter upon proctological examination?

In the first place, an inflamed, reddened and eroded anal canal will confirm the patient's complaint of irritation, soreness, burning, "fever," and pain in the anus which is aggravated by stool. In general, the more active the diarrhea, the more severe the anal irritation. An acute "attack of piles," may supervene when one or more hemorrhoids may become thrombosed or extruded. The entire anal ring may be everted in severe cases, and in most cases a variable degree of edema, redness, swelling, and inflammation may be encountered. An attack of prolapsed, strangulated, thrombosed hemorrhoids is brought on as frequently by an acute diarrhea as by the passage of a hard, constipated stool. Multiple fissuring of the anus, with eroded petechial spots or larger longitudinal breaks in the mucosa of the lower rectum and the skin of the anal canal, may occur so that the simple eversion of the anus during examination produces an active oozing of fresh blood. Marked spasm of the sphincter is the rule and one may not be able to examine the patient further. Palliative measures such as Sitz baths, warm applications, warm plain water enemas, or retention enemas of warm oil may be of value in alleviating the local condition so that examination may be completed a few days later.

When seen through the proctoscope, many cases of acute diarrhea will present nothing more than an active hyperemia of the lower 1 to 2 inches of the rectum. The blood vessels are engorged and stand out in a spider-web appearance to a degree greater than seen in the normal bowel. Small web-like patches of vessels may appear like a naevus with free intermingling of arteries and veins. After several days, the bowel may become edematous, and the glistening, translucent appearance of the mucosa may give one the impression that it is greatly thickened. This increased congestive vascularity is accompanied by spots and diffuse areas of bloody oozing which occurs by diapedesis. Ulceration of the surface does not develop unless the diarrhea is prolonged, when the mucosa becomes eroded and secondary infection of the bowel wall occurs. The bowel surface is easily traumatized, and half-moon shaped abrasions may be readily produced by the end of the instrument. Swabbing the surface may be sufficient to produce bloody oozing. The amount of mucous secretion is considerable and when mixed or streaked with blood, bacterial activity may produce a mucopurulent, bloody exudate even

though the bowel surface appears intact. The lower 2 to 3 inches of the rectum are usually affected and there is no sharp line of demarcation. Inflamed bowel gradually blends with normal bowel. Involvement of the entire rectum and extension into the pelvic colon should put one on guard and further examination and studies are indicated. This is likewise the case if an inflammatory process appears in the pelvic colon and seems to progress from there towards the rectum. These temporary, inflammatory reactions of the rectal mucosa should be observed and every effort should be made at an early date to separate them from the more serious disorders, mostly of a true infectious nature.

ULCERATIVE COLITIS

The diarrhea of ulcerative colitis may have an acute, chronic, or insidious onset. The acute case may have from 6-10, or even 20 stools a day, and the patient having a chronic insidious onset may note that he is now having 4-6 stools daily whereas three to four months previously he had only 1-2 daily movements.

This is a most serious disease of the digestive tract, and it may tax the ingenuity of the internist and gastro-enterologist before the diagnosis is made. Especially is this true in the regional and segmental forms of ulcerative colitis. However, from the diagnostic angle, we should be encouraged by the fact that 90% or more of cases of ulcerative colitis have their beginning in the rectum and pelvic colon. The fact that such a high percentage of these cases can be identified by proctosigmoidoscopy and culture should encourage all who see cases of diarrhea to examine the bowel by direct visualization, so that an early diagnosis of this disease may be made. It is thus obvious that a high percentage of cases of ulcerative colitis would therefore be correctly diagnosed at an early stage if they were examined with the sigmoidoscope.

If a patient consults one during the early phase of an ulcerative colitis, he may expect to encounter the following picture during proctosigmoidoscopic examination.

The mucosa of the lower rectum may appear inflamed similar to that described previously under acute diarrhea. There may be a gradual transformation into normal mucosa within the field of vision. However, the process is often more extensive and involves the pelvic colon beyond reach of the instrument. There is no early pathognomonic appearance, and a diagnosis of ulcerative colitis cannot be made from the visual aspect alone. A positive diagnosis may be made from cultures obtained at this time. As the disease progresses, the bowel wall appears more edematous and slightly thickened. The bowel wall is less pliable, the folds of mucosa stand out more firmly than usual and when the edge of the instrument scrapes any surface, bleeding readily occurs. The mucosa gradually develops a granular, glistening appearance, and minute mucosal abscesses appear. The abscesses are rarely larger than 1 mm. in diameter and they involve the bowel in a diffuse manner with a tendency for some areas to look a little patchy, appearing as if one had given a sudden "shake of pepper" to an area of the mucosa. The disintegration of these abscesses is accompanied by a surface ulceration which may be both discrete and confluent. This is a diffuse ulcerative process. The ulcers are usually small, 1 to 4 mm. in

size, and they are irregular. Numerous small ulcers may coalesce to form a larger shallow irregular lesion. Secondary invasion by the various organisms of the digestive tract tends to increase the incidence of the large irregular ulcerations. The intervening mucosa between patchy areas of ulceration is usually inflamed, edematous, and diffused with the small submucosal abscesses. Very little normal looking mucous membrane may be seen. This irregular ulceration is considered characteristic of ulcerative colitis at this stage. Cultures taken at any time during the pre-ulcerative phase or during the ulcerative stage may reveal a multiplicity of organisms. Identification of the responsible organism, or group, presents a bacteriological problem beyond the limits of this paper. It is felt, however, that Bargen has made the most outstanding contributions to this work that have been presented within recent years, and for that reason "Ulcerative Colitis" of the Bargen type is being discussed.

This early stage of ulcerative colitis is definitely a medical problem; no single mode of therapy is applicable. A rational, symptomatic management, as in tuberculosis or cardio-renal disease, is indicated.

The disease can be followed very readily, in its progression or regression, by the use of the proctosigmoidoscope. The proctologist and the roentgenologist can usually demonstrate the extent of the disease and some index of its activity and the degree of infection may be gathered by frequent sigmoidoscopy. Beyond reach of the instrument, the course of the disease is best followed by the roentgenologist.

The chronic, recurrent type of ulcerative colitis presents a different proctosigmoidoscopic picture. As a result of the chronic infectious process many unique and bizarre findings may be observed. Areas of new and old ulcerations are interspersed with areas of healing, scarring, and contracture. Irregular, depressed, pock-marked scars may be seen between areas of shaggy, necrotic tissue protuberances and mucosal folds. The bowel appears as a semi-rigid tube and the mucosal folds do not roll back and away from the instrument as it is being introduced, nor do they show much tendency to roll and "pout" into the lumen of the instrument. When the lumen is contracted, there occurs resistance to the passage of the instrument and bleeding follows as the granular surface is touched. Exudate and sloughing, and irregular patchy areas, may be seen. The ulcerated bowel rarely presents any areas of normal mucosa, and in contrast to the small miliary ulcerations in the early case, the ulcerations are larger. They may attain the size of 1 to 2 cm., due to secondary infection and loss of bowel resistance. The discrete, serpiginous, and confluent ulcerations of this chronic process may give one the impression of looking at a relief map with its geographical irregularities. The term "geographical ulcerations" might well be applied to many of these cases. This chronic phase of ulcerative colitis may present some of the complications peculiar to this disease. We mention particularly stenosis and a tendency to polypoid degeneration with or without malignant changes. Hemorrhage and ulcerative perforation of the bowel are omitted from a proctologic standpoint, although one should use extreme caution in manipulating an instrument in the scarred, contracted bowel, lest accidental perforation occur.

The stenosis of the bowel develops as an irregular,

diffuse process with very little tendency to the formation of the "diaphragmatic" type of stricture. The long, irregular, tubular narrowing is the rule when stenosis does develop. The degree of stenosis is often indicative of the duration and the severity of the disease.

Cases of virulent infection or of long standing are prone to develop a polypoid degeneration of the mucosa. The mucosa between healed and unhealed areas has a tendency to pile up so that rough, irregular fragments may be seen. In other areas, the mucosa may infold upon itself and produce an actual cystic inclusion of cells, secreting mucus, which appears as a smooth, pinched-up mucosal bud which is commonly dark red in color. One has the impression of looking into an inflamed, moth-eaten tube, irregularly studded with small polyps. The bowel which shows any evidence of polypoid degeneration should be carefully watched, and any suspicious areas within reach of the proctosigmoidoscope should be subjected to biopsy. A considerable number of patients affected with polypoid degeneration exhibit malignant change, provided the patients live long enough to have such transition take place.

It is not the purpose of this paper to discuss any of the characteristics of the diarrhea or the stools in these cases. The proctoscopic findings are presented as an aid to the etiologic diagnosis of a diarrhea. One should be able to make a diagnosis of ulcerative colitis from the visual appearance of the bowel. Stool cultures from material obtained through the instrument, direct smear examination of the scrapings and the biopsy examination of tissue bits are indicated as an aid in establishing the diagnosis.

AMEBIASIS

Amebiasis should be considered as a disease entity which may have as one of its manifestations an amebic colitis accompanied by diarrhea. The colonic manifestations of amebiasis may vary from the acute fulminating type of ulcerative colitis to those atypical clinical conditions known as "irritable colon," "spastic colitis," "mucous colitis," etc.

The differentiation of amebic colitis from types of infectious colitis often presents considerable difficulty. I wish to emphasize that the ultimate diagnosis of amebiasis rests upon the identification of the pathogenic ameba or their cysts in stools, or scrapings obtained at proctoscopic examination. In the presence of an outbreak of dysentery in a community one may make a presumptive diagnosis of amebiasis. This should be confirmed by the visual findings of bowel ulcers which will be described later; however, the final decision depends wholly upon isolation of the pathogenic organism or its cysts. Cultural and serological methods of diagnosis are beyond the limits of this paper.

Proctosigmoidoscopic examination in a suspected case of amebic dysentery will ordinarily be positive in the early case, although it is less frequently positive than it is in ulcerative colitis. The fresh case with active diarrhea is more liable to show ulcerative lesions than the older case. Hinman and Kampmier (6), in a study of four hundred cases of active amebic dysentery in New Orleans, reported visible ulcers in 261 cases out of 299 proctoscopic examinations. This high incidence of visible ulcers is not seen in the older

cases. The ulcerative lesions of amebiasis may occur anywhere in the colon; their absence in the lower visible segment does not rule out this disease. The early inflammatory stage of amebic colitis cannot be differentiated from any other active lesion. When ulcerations develop, they are about 3 to 5 mm. in diameter. They are superficial, usually discrete and they may be scattered in patches about the mucosa. They are larger than the ulcers of ulcerative colitis. The superficial ulcer has irregular, sharply defined, ragged, and undermined edges surrounded by a halo of inflammatory change. As the ulcer deepens, the inflammatory reaction creates a nodular projection of the mucosa, the center of which is occupied by the ulcer. Its surface is covered with a thick purulent exudate mingled with necrotic material and mucus and vegetative forms of the ameba. This "umbilicated" ulcer is considered pathognomonic for amebiasis. The intervening mucosa is slightly injected and hyperemic, but it will ordinarily appear more normal than in ulcerative colitis. Miliary abscesses as seen in ulcerative colitis, are not present unless a burrowing, secondary infectious process develops in the area of amebic ulceration. This may appear as a "satellite" formation around the edge of an individual ulcer. Direct examination of the material swabbed from these ulcers will ordinarily reveal the vegetative form of the ameba.

The older cases of amebiasis with the larger, confluent ulcerations, that have developed as a result of secondary infection cannot be visually differentiated, with any degree of certainty, from the older case of infectious ulcerative colitis. Here one notes the same type of secondarily infected, large, irregular, serpigenous, and "geographical" ulceration. Coalescence of ulcers may produce a large, denuded surface, and, in cases of any duration, the infiltration of the submucosa and the remainder of the bowel wall tends to produce rigidity. Firm, irregular stricture is unusual unless an inflammatory and proliferative lesion—an amebic granuloma—has developed. Such is uncommon; only by biopsy, "therapeutic" test, or clinical course may it be differentiated from malignancy. Stenosis of the bowel of the diffuse type may occur, and here the long "moth-eaten," ulcerating tube may be observed.

Ulceration and fissure formation may occur about the anus and an amebic infestation of the buttocks may be, indeed, a disabling condition.

While the proctoscopic picture of a few, discrete umbilicated ulcerations is regarded as pathognomonic by some clinicians of amebic colitis, one must remember that the lesions although they exist may not always be visible at sigmoidoscopy. Experienced proctologists may make the diagnosis of amebiasis from the endoscopic findings alone, but however, experienced the clinician may be, the final proof still rests upon the identification of the pathogenic ameba. When scrapings from the mucosa do not exhibit the organism, in an instance where the diagnosis of amebiasis is highly probable, stools secured following free catharsis by epsom salts usually reveals both the vegetative or encysted ameba if such stools are properly collected and examined by an experienced laboratorian.

One should be mindful of the simultaneous presence of non-amebic ulcerative colitis in instances of amebiasis, hence one should take the routine scrapings,

cultures, smears, etc., so that the material can be studied with respect to the organisms of Bargen, Flexner, Welch, Sonne, etc.

MALIGNANCY

Diarrhea has a variable incidence as an early sign of malignancy of the rectum and pelvic colon. However, if one is to consider an alteration in the stool habits of the individual together with the inception of alternate periods of diarrhea and constipation as a new experience for the patient, he has suggestive information respecting bowel irritation and obstruction. When the lesion causing such change in stool habits is located in the rectum or pelvic colon, it is frequently malignant. Our statistics show that from 10 to 25 per cent of patients who have terminal colon lesions of a malignant kind, exhibit diarrhea as an early symptom. Further, there has been prolonged treatment carried out for dysentery or diarrhea without even a digital examination having been performed; in some instances, the patients themselves, have asked the physician to examine the rectum. Blood in the stool, either with or without diarrhea, may be encountered in 80 to 90 per cent of these cases. Needless to say, many patients were considered as having only hemorrhoids. Even though there has been much publicity in respect to the frequency with which simple, bleeding "piles" in the middle aged are actually instances of malignancy, the profession still neglects routine digital examination of the rectum. In the histories of our patients with low colon malignancy, constipation was recorded in from 50 to 75 per cent.

Diarrhea, constipation, alternate diarrhea and constipation, and blood in the stool, raise questions whose answers will be dependent upon the type of individual we are investigating. The recognition of these symptoms will vary as is attested by the patient who states that he does not have diarrhea, but that he goes to stool 6-8 times a day "to get rid of a little wind and mucus." If we asked this patient if he had frequent movements, the answer would be "Yes," but if we ask him if he had diarrhea, the answer would be "No."

We should consider the symptoms alone of anorectal disease as untrustworthy and proceed accordingly. The symptom diarrhea, with or without bloody stool, is unreliable except as it directs attention to the fact that both a digital and proctosigmoidoscopic examination of the rectum and pelvic colon is indicated. In respect to roentgenological evidence of malignancy, the following comment by Jones (7) seems pertinent—"As the average roentgenologist can make a correct diagnosis of carcinoma of the rectum in only 40 per cent of cases, it is evident that it is hardly reasonable to depend upon such a method when proper digital and proctoscopic examination will give the diagnosis in 100 per cent of cases." This statement is true in the experience of all who have occasion to deal with carcinoma of the rectum.

In discussing rectal malignancy, it is felt that the large, proliferating, fungating, necrotic cauliflower mass does not demand description here. When proven by biopsy, the diagnosis is settled. The small, discrete, ulcerative lesion should be considered malignant until proven otherwise. These irregular, ulcerative, excavating lesions nearly always appear as a single crater with slightly raised, indurated, irregular borders. The immediate surrounding area may be slightly inflamed, but the adjacent and remaining mucosa is normal.

Lesions less than 1 cm. in diameter usually do not show any fixation. This small ulcerative process must be differentiated from a solitary amebic ulcer, a tuberculous lesion, and the rare and unusual ulceration of a diverticulitis. Biopsy is indicated; but we still must not overlook the presence of an amebiasis in the presence of a malignancy.

A solitary, adenomatous, proliferating mass, with or without ulceration should be given the same consideration as a solitary ulcerative lesion. Likewise the small, flat, slightly elevated, rough plaque without a pedicle, ulceration, or necrosis demands biopsy.

The scirrhus type of malignancy which may be located in the pelvic colon is apt to present some diagnostic difficulty. In passing the proctosigmoidoscope, one may encounter an abrupt stenosis of the bowel. Similarly a particularly resistant angulation of the bowel may be met even in the absence of pathology. Here it is important to prove whether or not the lumen is patent and to know, if possible, the calibre of the lumen. We should know if the diameter of the lumen is abnormal, and this calls for a knowledge of what variation there may be from normal. It is absolutely necessary to know why the instrument cannot be introduced its full length. These scirrhus lesions present a fairly sudden, uniform stenotic process. Their mucosal surface may exhibit a proliferating lesion, but more commonly there is a diffuse, sharply localized inflammation and ulceration accompanied by a firm unyielding stenosis of the bowel. There are times when one cannot see anything as the bowel mucosa folds in ahead of the instrument just as one approaches the area of stenosis. At times, by cautious air inflation, the folds may be obliterated and the lesion seen. In the absence of visible pathology biopsy is uncalled for. The X-ray films may reveal the typical "napkin-ring" deformity.

A word regarding the value of proctoscopy and biopsy in rectal malignancy.

Even the clinician of experience has been deceived by the tuberculous, amebic, luetic, and other specific and non-specific granulomatous lesions of the rectum and pelvic colon. The inflammatory, stenotic mass associated with diverticulitis may produce a picture resembling malignancy; many times, it is not until the pathological specimen is studied microscopically that the differentiation between malignancy and inflammation is possible.

Biopsy should be considered indispensable to the routine proctoscopic examination for malignancy. One specimen, properly secured, should be sufficient but additional specimens should be obtained when there is doubt. Biopsy should differentiate the granulomas and inflammatory masses from malignancy. An index of their malignant activity may be obtained by histopathological study. The lesion whose index shows it to be highly malignant requires prompt, radical treatment. Broders' classification and grading of malignancy, when properly interpreted and evaluated, is of considerable assistance in these cases.

Proctoscopy should determine the site, gross physical characteristics and amount of local fixation of malignant or other lesions. The degree of fixation may be estimated by cautiously manipulating the end of the instrument if the lesion is beyond reach of the index finger. The degree of obstruction may be accurately determined through the proctosigmoidoscope and, in properly selected cases, the passage of an irrigating

catheter through and above the lesion, may be of some value in facilitating "decompression" by permitting the passage of gas and bowel contents.

TUBERCULOSIS

In the vast majority of instances, the development of a tuberculous dysentery is secondary to tuberculous foci elsewhere in the body. The clinical picture of an alimentary tuberculosis should be substantiated by fluoroscopic and roentgenological evidence, and when possible, by proctoscopic examination. One should remember that the finding of tubercle bacilli in the stool is not diagnostic of alimentary tuberculosis. Such bacilli may have been swallowed from a lung focus. However, if there is an ulcerative or (rarely) a hyperplastic lesion in the rectum or pelvic colon, biopsy will be of some value in determining whether or not it is tuberculous.

The primary lesion or tubercle is rarely seen during proctoscopy as these patients are usually not investigated instrumentally until an active dysentery has developed. When a tuberculous ulcerative process of the rectum and pelvic colon is encountered, one may expect to find anything from a single ulcer to a multiple, irregular lesion. The ulcers are of various shapes and sizes; they do not tend to follow any axis of the bowel, as has been noted when the ileum is involved. The ulcers are ragged, irregular, and not sharply defined. They vary in size from 2 mm. to many centimeters, and the large ulcerations may be the result of coalescence of several adjacent ulcers. The base of the ulcer is rough and irregular and it may be covered by a purulent, necrotic material. This dirty, grey, tenacious slough is very difficult to dislodge. These lesions progress slowly along their periphery; the mucosa immediately around the edge of the ulcer is slightly inflamed. The intervening mucosa may be clean. These lesions do not tend to produce so great an inflammatory change accompanied by stenosis, stricture, and granulomatous formation as do some of the other granulomatous affections.

Smears for staining and material for culture should be secured. Biopsy and histopathological study are indicated inasmuch as many of the granulomatous lesions have bizarre forms and their etiology can be determined only by expert histologic study.

BACILLARY DYSENTERY

In discussing bacillary dysentery, one should remember that the acute phase of bacillary dysentery may present findings in the rectum and sigmoid; findings which are no more distinctive than those which occur in any disturbance where acute diarrhea is a symptom. This is due to the fact that the diarrhea of an acute bacillary dysentery has often subsided within 10 days to 2 weeks. The more intense and severe lesions of acute bacillary dysentery go beyond the stage of hyperemia, bloody oozing, and edema. A diffuse inflammatory process of the mucosa and submucosa presents a cherry-red appearance with free oozing of fresh blood. The picture resembles that which has been described as a "hemorrhagic proctitis." The spongy-red, bloody surface of the bowel soon exhibits a diffuse superficial ulceration of the mucosa. The ulcers are small, 2 to 3 mm. in diameter; they are superficial; they tend to be discrete; their edges are smooth; and they involve only the mucosa. This may

be observed during the early days (5 to 10) of the disease, and the lesions may heal rapidly thereafter. This affection must be distinguished from that of acute diarrhea, and during the acute stage, stool cultures are indicated. Amebiasis, ulcerative colitis, and other infectious dysenteries require consideration, although the diffuse, severe, hemorrhagic appearance of the bowel in bacillary dysentery is seldom encountered in other conditions. A positive stool culture adequately differentiating the causative organism may be obtained during the early stages of the disease. As the ailment passes into the chronic phase, isolation of the specific organisms is almost impossible.

The patient who has developed a chronic bacillary dysentery is very commonly a diagnostic problem. The physician, internist, and gastro-enterologist who suspect this condition in some of their intractable cases of diarrhea and "colitis" may be greatly surprised when they perform agglutination tests on these patients. The recent work of Felsen (4, 5) has brought this disease to our attention rather forcefully, and his work appears to give additional and new value to the well-known ideas of Hurst.

The proctoscopic findings in cases of chronic, bacillary dysentery can rarely be distinguished from those of ulcerative colitis, hence, routinely one should test the blood serums of these patients by the approved methods of agglutination. The reader is referred to the proctoscopic description of the chronic phase of ulcerative colitis. It should be kept in mind that during the chronic phase of bacillary dysentery, the culture obtained by sigmoidoscopy will usually be negative for the various strains of *B. Dysenteriae*; whereas the culture for chronic ulcerative colitis, of the Bargen type, the organism is more readily found.

The segmental forms of bacillary dysentery are commonly and easily confused with ulcerative colitis, tuberculosis and regional ileitis as described by Crohn (2).

POLYPOSIS

Among the earliest symptoms presented by patients affected with disseminated polyposis of the colon, are the various types of diarrhea accompanied by griping and cramp-like pains of the lower abdomen. The diarrhea associated with polyposis may be intermittent, but the active period of the affection is usually accompanied by diarrhea to a degree that the patient experiences 10 to 20 stools daily. An occasional case begins with a bloody diarrhea, but usually the patient will recall that he has recently experienced stools containing considerable mucus and that this has been followed by the present bloody diarrhea. Until blood appears in the stools, most of the patients do not consult a physician. Especially is this true when patients consider that the blood is from "piles." Disseminated polyposis of the colon should be given consideration in cases of bloody diarrhea, and efforts should be made to determine the type of lesion which is present.

We are interested in two rather distinct types of polyposis, namely: 1. the hereditary or familial type; and 2. the acquired or inflammatory type.

The hereditary or familial type of polyposis as discussed by Erdmann and Morris (3), Wesson and Bargen (11), Yeomans (12), Soper (10), Mayo and Wakefield (8), and McKenney (9), usually appears in patients younger than 30-40 years of age. The family history is important. The patient should be questioned

as to whether a similar condition has been experienced by his mother, father, brothers, or sisters, or other close blood relatives, as has been suggested by McKenney (9). This type of colonic polyposis might well be named "familial intestinal adenomatosis," inasmuch as these lesions are true adenomata. The diffuse disseminated lesion, which involves the entire bowel from the anus to the ileocecal valve is the usual type encountered, although a patchy or segmental distribution is not unknown. Roentgen studies, especially with the air contrast enema technique, will demonstrate the extent of the lesion. Carcinomatous change may be identified by roentgenograms in many cases, but when the lesions are accessible by proctoscopy, tissue should be obtained by biopsy.

As the majority of these lesions extend from the anus to the cecum, a digital and proctosigmoidoscopic examination will usually demonstrate a very distinctive picture. The early case, without marked inflammation and induration, will feel soft and pliable with an occasional wart-like nodule being felt on the mucosa. One may palpate, singly or in patches, small pea sized growths arising from the mucosa. When inflammation has ensued the bowel wall becomes indurated and firmer, and one has conveyed to the examining finger a "cauliflower-like" feel. However, the large proliferative cauliflower mass is absent. The entire bowel wall in all of its circumference is roughened. Inasmuch as the polyps vary from 2-3 mm. to 1 cm. or more in diameter, one detects these tumor masses in size varying from that of a pinhead to a grape or walnut. Scattered over this roughened surface, a few large pedunculated growths may be felt to move freely to and fro by the examining finger. Proctosigmoidoscopic examination will reveal that the mucous membrane is diffusely studded with these growths whose form, size, and appearance will vary. Usually the bowel is injected and shows some evidence of inflammation so that one may observe small nodular "bumps" on the mucosa that stand out in relief as pale spots between smooth areas. Finger-like projections and lesions with relatively long pedicles may be interspersed between areas of smoother mucosa. As the condition progresses, infection, inflammation, and ulceration follow. Degenerative changes and malignant transformation accompany this condition, so that the old secondarily infected, ulcerated, and degenerated lesions are dark hemorrhagic red. Some of the larger polypi may slough off leaving a granulating ulcer at the base. Continued oozing of blood results in a marked anemia.

There is a definite feeling among many members of the medical profession that the majority of these cases of disseminated polyposis of the colon will undergo malignant change if the patient lives long enough. There is increasing evidence to substantiate this opinion if the lesion is identified as being of the "familial" type. For this reason, patients should be subjected to frequent roentgenological studies so that the nature and the extent of the ailment may be recognized. If malignant change appears, such radical therapy as is technically possible should be instituted in the hands of a competent surgeon.

The second type of disseminated polyposis of the colon has been designated by Erdmann and Morris as the acquired type. Bargen and Wesson have called it "post-inflammatory polyposis." Both groups agree

that the familial type differs from the acquired type. It should be emphasized that the acquired or inflammatory type of polyposis is not a true adenomatous disease. It is, in reality, a "pseudopolyp" formation. Such cases are derived from the long standing effects of ulcerative colitis, amebiasis, bacillary dysentery, bilharziasis, et cetera, in which buds and polypoid excrecences or "pseudopolyps" have developed. In this type of polyposis, the colon presents a moth-eaten ulcerated tube irregularly studded with polyps. More ulceration is present than in the former type and very little evidence of normal mucosa is apt to be seen. This is definitely a more "ragged" process, appearing as a chronic ulcerative colitis in which there is a tendency to form inflammatory buds of tissue. This is a secondary inflammatory change of the bowel associated with the infectious dysenteries; it is not a true adenomatosis.

It is suggested that the former "familial polyposis" be considered a true adenomatosis coli and that it be designated by the term "Familial Intestinal Adenomatosis," and that the name be further qualified by the location; cecal, transverse colon, pelvic colon, rectum; and by the changes present; i.e. inflammatory, degenerative, malignant, etc. Such nomenclature would indicate the status of the adenomatous process in any case at any given time.

The second type of disseminated polyposis could be well designated as "Acquired Inflammatory Polyposis."

ADENOMA

The diagnosis of a single adenoma of the rectum and pelvic colon is as important as the diagnosis of malignancy, for it has been repeatedly indicated, and proven, that many cases of solitary adenoma become malignant. Adenoma should therefore be considered as the precursor of malignancy and appropriate treatment instituted.

The first intimation of a rectal adenoma which a patient may experience is a sudden, profuse, and often alarming hemorrhage. Close questioning may reveal that there has occurred an intermittent passage of mucoid stools previously. Diarrhea is not ordinarily a prominent symptom noted by the observant patient, although the passage of mucus may be observed. In children when an adenoma is located close to the anal outlet, there may be obstipation, straining, bleeding, and the appearance of a grape-like tumor mass at the anal orifice.

The majority of single adenoma of the colon occur in the rectum and pelvic segments of the colon; therefore, they are palpable or visible to digital and proctosigmoidoscopic examination. Digital examination should determine the size, location, fixation, and induration of the lesion. Visualization of the adenoma should determine the size of the lesion, the character of its attachment and the presence of ulceration or marked proliferation. These lesions will vary in size from 3-4 mm. to many cms. in diameter. They may be smooth and shiny or rough and warty. The adenoma with the definite, small, soft pedicle without surface ulceration or proliferation, may be considered as benign although biopsy is indicated. The flat, button-like lesion is more apt to be malignant than is the long grape-like tumor. The large adenoma having a rough, irregular, cauliflower-like surface, without ulcerative spots or areas of marked proliferation, should be considered malignant until proven other-

wise. Biopsy of tissue from several portions of the lesion and its pedicle should be performed. The appearance of ulceration or proliferation on any of these lesions should be regarded as evidence of malignant change until proven otherwise.

These lesions require little visual description as their appearance is characteristic. More than one adenoma may be present, and the clinician is urged to make his proctosigmoidoscopic examination complete by inspecting the entire bowel within reach of the instrument. Roentgen study of the colon may be required before one may say that the affection is, or is not, localized to the visible portion of the bowel. In regard to adenoma and polyps, barium enema followed by the air contrast technique for demonstrating the mucosal patterns is of utmost value.

SUMMARY

This communication attempts to present the proctological significance of diarrhea, or alteration in stool habitus, from the standpoint of diagnosis by direct visual inspection of the bowel mucosa. It is hoped that the general practitioner, the internist, the gastroenterologist, and others will recognize that the judicious use of the proctosigmoidoscope should be part of their diagnostic procedures. Endoscopic examination of the anus, rectum and pelvic colon permits direct visualization of the terminal gut; there is no substitute for it. As with other investigative procedures, it is not always possible to arrive at a final diagnosis during the first examination; particularly if attempt is made to recognize pathology when the bowel has not been thoroughly emptied of all forms of residue. One cannot too severely condemn efforts at diagnosis made when the patient has not been properly prepared, or when the examiner does not completely and thoroughly inspect all of the mucosa within reach of the instrument. Stool examination should be augmented by direct smear and culture from the mucosal surface. Scraping should be examined grossly and microscopically more frequently than is the custom. Biopsy is indicated more commonly than is practiced. The presence of more than one disease, i.e. amebiasis complicating malignancy, should be kept in mind in the obscure and unusual case. The term "colitis" will mean something if we can demonstrate the cause which is truly producing inflammation of the bowel. Only in such events is it possible to have exhibited specific therapy for specific disease processes. Roentgenological investigation should be the harmonious accompaniment to the special diagnostic procedures common to the trained proctologist.

The Importance of Recognizing Contracted Anus

By

LOUIS A. BUIE, M.D.*

and

WINFIELD L. BUTSCH, M.D.†

ROCHESTER, MINNESOTA

THE term "contracted anus" as used in this report designates a condition characterized by an inelastic, fibrous stricture of the anus, including the subcutaneous and muscular components, due to infection which gains entrance to the tissues through the anal crypts. Other pathologic conditions, such as anal fissure, anal fistula, hemorrhoids, hypertrophied papillae, and so forth, may occur conjointly with this disorder, but it should be understood that instead of causing contracted anus, they occur as a result of the infection which produces it.

One hundred consecutive cases of contracted anus in which patients were operated on at The Mayo Clinic are the subject of the following remarks. Only cases which presented this disorder without significant complications are considered in this series. Cases of contracted anus in association with anal fissure, fistula, hemorrhoids, and other pathologic disorders of the anus and lower portion of the rectum are not included in the report, nor are those in which contractural deformities resulted from previous rectal operations. In this series, however, are included those cases in which there were external tags, hypertrophied papillae, and small, internal hemorrhoids which occurred concomitantly with the process which was responsible for contracted anus.

One hundred years ago Herbert Mayo wrote of "cases in which spasm of the sphincter produces long-continued and most serious suffering; in which the anus becomes permanently contracted and hardened, constituting therefore a permanent stricture, and generally combining both permanent and spasmodic contraction." Miles recognized this condition of the anus; he called it a "pecten band" and regarded it as a distinctly pathologic condition resulting from fibrosis of the "submucosa" following long-continued passive congestion in the area associated with internal hemorrhoids. According to Miles, another cause of "pecten band" is passive congestion due to pressure on the veins of the rectum, this pressure occurring in constipated persons with a rectum habitually loaded with feces. Abel reiterated Miles' theory of origin, in a recent paper, and added the conception that long-continued spasm of either sphincter of the anus will cause passive congestion and subsequent deposit of fibrous tissue in the submucosa, forming a pecten band.

Zorraquin called the condition "myositis sphinctera." It is caused, he said, by slight infections of the "anal or rectal mucosa" which later impregnate the external sphincter and produce scars. In other cases the process may be less extensive and involve only the mucosa and submucosa with accompanying hypertrophied papillae and skin tags.

Rieder and Muller believed contracted anus to be due to an inability of the internal sphincter to open. Inflammation of the rectal wall, in their opinion, interferes with conduction in the fibers of the "pelvic nerve" located there. As the function of the "pelvic nerve" is to open the internal sphincter, this opening cannot be accomplished and the sphincter remains in a contracted position. They did not regard this contraction as a state of spasticity; instead they considered the opening of the sphincter to be the active phase and the contracted position the resting phase of the muscle.

Carnett recognized a chronic, undue spasticity of the external sphincter as a cause of constipation. He stated that, "in many cases, however, no irritative lesion can be found to account for the sphincterismus."

Hill and Hayden found their explanation for anal contraction in embryologic maldevelopment. They were of the opinion that mesoblastic connective tissue persisting between the hindgut and proctodeum caused in severe cases an imperforate anus, in milder cases an anal stenosis. We found in the records for the three years studied, one case, that of a child three months old, which exemplified this condition.

We agree with Zorraquin that anal contraction can exist as a fibrous deposit beneath the lining membrane of the anal canal or as a fibrosed external sphincter. It is possible that the fibrous band described as the pecten band may exist, but we have not been impressed with any instance in which this condition occurred independently of similar involvement of the sphincteric muscles surrounding the anus. It is possible that the deposit of fibrous tissue within the substance of the sphincter may occur to such a minimal degree that the pecten band appears to occur alone; but that this fibrosis could actually be limited to the subcutaneous tissues of the anus, to the exclusion of any of the adjacent tissues, seems highly improbable. In most of the cases of contracted anus which we have observed, in addition to the fibrous band the anal sphincters, or a portion of them at least, are found to be scarred and unyielding.

DIAGNOSIS

Contracted anus is suggested when a patient complains of inability to evacuate the rectum. Most of these individuals are loath to admit that they are constipated and prefer to dwell on the fact that there is a "stoppage" at the outlet of the rectum which interferes with the expulsion of the rectal content. They complain that even when they are able to defecate they are left with a sense of incompleteness and the stools are of small caliber. There is usually a sense of fullness in the rectum and the patient is troubled with a frequent desire to defecate. He has usually made use of a large portion of the innumerable laxatives and

Submitted September 13, 1937.

cathartics, all of which ultimately lose their effect and leave him in a worse dilemma than that in which he found himself previously.

The diagnosis can easily be made. On examination it will be found that the anus is contracted. It is impossible to separate the anal margins so that the first portion of the anal canal can be visualized, as may be done in normal individuals. When an attempt is made to perform digital examination, a sensation as if the finger is being pressed into the lumen of an unyielding, bony ring is imparted. Often the caliber of the ring is so small as barely to admit the tip of the finger. A significant sign is obtained when, either by pressing the finger tip against the anal margin, or when it is possible to insert the finger within the anal canal, any pressure which moves the anus will move the tissues adjacent to it so that the whole perineum also appears to move. This indicates that the contraction is not limited to the lining membrane of the anus, because in such a case the thin tube-like stricture will slide in and out of the muscular circle without moving the adjacent parts. Usually there will be accompanying pathologic changes, although it is possible for contracted anus to exist with no evidence of gross disease in the anus or about its margins. Only nine of the 100 cases studied in this series failed to show some other pathologic change. Infection of the anal crypts, that common denominator of such a great part of benign anorectal disease, is the cause of contracted anus. Internal hemorrhoids, which Miles believed to be the causative factors, spring from this same infective process that causes the fibrosis of contracted anus.

ANALYSIS OF CASES

In 27 per cent of our cases contracted anus was found with associated internal hemorrhoids, but hypertrophied papillae were also present as another evidence of the infection that caused the disorder. Internal hemorrhoids, it is true, were most commonly associated, being present in 45 per cent of the cases. Frequently hypertrophied papillae, external skin tags, or anal scars were also present in cases in which internal hemorrhoids were present, which is additional evidence that infection is a common root of all.

Eighty-four per cent of our patients were women. The severest type of constipation was present in eighty cases. A number of patients found it necessary to make pressure on the perineum as an aid in expelling the stool. Thirty-four per cent of the patients were in the age decade from forty to forty-nine years, which was more than twice the number in any other decade.

A striking fact was that 56 per cent of the patients had in addition been diagnosed as having nervous exhaustion, which diagnosis is not applied indiscriminately to individuals of a nervous type. It is applied only to patients who exhibit to an advanced degree an irritable weakness syndrome characterized by a multiplicity of complaints without positive physical findings.

TREATMENT

It is necessary in cases of contracted anus to enlarge the anorectal outlet, and inasmuch as the deposit of fibrous tissue occurs both in the subcutaneous tissues of the anus and diffusely in the anal musculature, simple incision of the so-called pecten band is insufficient. It is necessary to overcome the contractual influence of the fibrous deposits by stretching, and this

procedure should be carried out in the most careful and intelligent manner. The operation cannot be performed without anesthesia, and at the clinic we have employed sacral anesthesia for this purpose; by this method the effect of muscular spasm is entirely eliminated and usually any resistance which must be overcome is due to fibrous development.

Following the customary preparatory procedures, consisting of irrigations to empty the lower part of the rectum and the application of tincture of metaphen to the anal and perianal tissues, the rectal outlet is dilated in the following manner: The index finger of one hand is inserted through the anal canal, using whatever force is necessary to overcome any constricting influence. While this finger is held in place, the index finger of the other hand is forced slowly in beside the first until the tips of both fingers are well within the lower rectum. Further stretching is then accomplished by slowly but firmly flexing both fingers at the first and second joints. This maneuver draws the anus up higher on the third phalanges of the fingers where the diameter is greater. Next, the two index fingers are withdrawn and the index and middle finger of one hand are inserted, after which the index finger of the other hand is again forced in beside them and the maneuver is completed, as in the former instance, by flexing all three fingers. The amount of dilatation afforded in this manner will usually suffice; if it is considered insufficient, both fingers of both hands can be inserted and flexed as described. The most valuable feature of such dilatation is that the maneuver is likely to proceed slowly, and in that way the surgeon avoids the complications which often occur as a result of the usually hasty method of stretching the anus.

If there are any accompanying pathologic deformities, such as hypertrophied papillae, skin tags, and so forth, these should, of course, be excised after dilatation has been completed. The postoperative management of such a patient is of extreme importance, and if this program is carried out properly it will prevent those unfortunate recurrences which sometimes follow this method of treatment.

Each day after the bowels have acted, the rectum is cleansed by an irrigation which consists of plain water at 110° F. which is given through a small, soft rubber catheter well lubricated with a water-soluble non-irritant lubricant. Only 2 to 3 inches of the catheter are inserted into the rectum. The patient is cared for each day until the wound produced by dilatation or removal of papillae, tags, and so forth is entirely healed, or until it is in such condition that it will need no other care than that which can be carried out by the patient unassisted. Each day following the evacuation of the bowel and the irrigation, the anal canal and the wound are cleansed by irrigation with witch hazel. This is accomplished with an ordinary 20 c.c. syringe, a connecting rubber tube and a perforated irrigating tip. Many solutions other than witch hazel may be used as for example, an aqueous solution of metaphen (1:500), a saturated solution of boric acid, dilute potassium permanganate solution, and so forth. If the wound is sensitive, it is comforting to dust into it a generous amount of parathesin or anesthesin (ethyl aminobenzoate). Finally a piece of cotton of suitable size is lightly tucked into the orifice of the anus or into the margins of the wound.

A full-residue diet supplemented by agar is given

immediately after operation in order to provide bulk in the stools. No mineral oil or cathartics are given.

COMMENT

While contracted anus does not occur in a great number of cases of constipation, its diagnosis offers the possibility of definite and quick relief. The treatment of chronic constipation has all too frequently been confined to general measures. Usually the physician lays down a barrage of advice concerning proper habits, exercise, diet, and recreation. The patient listens and tries vainly to fit the ideal scheme into the limitations of his crowded existence. Often when he is able to comply with all of the requirements prescribed by the physician he is unsuccessful because of

the existence of the anal deformity which has been the subject of this discussion. The results of the treatment of the patients in this series have been satisfactory.

The Effect of Aluminum Hydroxide Cream on Absorption from the Gastro-Intestinal Tract

By

J. M. BEAZELL, C. R. SCHMIDT

and

A. C. IVY*

CHICAGO, ILLINOIS

DURING the past year a number of reports have appeared in the literature concerning the value of colloidal aluminum hydroxide cream in the treatment of peptic ulcer and chronic colitis. Since aluminum hydroxide is employed extensively as an enzyme adsorbent, it appeared possible that when administered orally it might interfere with digestion by adsorbing gastro-intestinal enzymes. If this were true, its prolonged administration might be expected to lead to nutritional deficiencies.

The effect of adsorbing agents on the activity of a given enzyme depends on a number of interacting factors. A given adsorbing agent may quantitatively remove an enzyme from solution at one pH while it removes it incompletely or not at all at a slightly different pH. The order in which enzyme, substrate, and adsorbing agent are mixed also effects the degree of adsorption. Further, under certain conditions, an adsorbed enzyme may be as active as it is in the free state. Since the multiplicity of conditions encountered in the gastro-intestinal tract during normal digestion can not be duplicated in a test tube, results obtained in vitro can not be unequivocally used as a basis for anticipating in vivo results. Therefore, although preliminary in vitro experiments showed that aluminum hydroxide does not significantly alter the activity of trypsin or pancreatic lipase when the enzymes are permitted to act under optimum conditions, animal experiments were undertaken.

METHODS

In vitro experiments: The tryptic and lipolytic activity of a pancreatin preparation of known potency was determined with and without the addition of an excess of aluminum hydroxide. The non-protein nitro-

gen method described by Northrop (1) was used for measuring tryptic activity. Lipase was determined according to the method described by Cherry and Crandall (2).

In vivo experiments: Three dogs were given 500 grams of a standard diet daily for a period of 16 days (nitrogen content of diet 0.75%, fat content 3.5%). To insure uniformity, the diet was made up in a single batch large enough to last throughout the experiment. The experiment was divided into two eight day periods. During the first period the unsupplemented diet was fed (control period). During the second

TABLE I

Dog No.	Control Period—5 days			Aluminum Hydroxide Period—5 days		
	Total Wet Weight of Feces	Total Nitrogen	Total Fat	Total Wet Weight of Feces	Total Nitrogen	Total Fat
1	639	9.5	12.6	722	10.4	12.2
2	461	2.6	11.5	575	8.9	13.8
3	561	10.7	11.7	597	9.5	12.4

period 80 c.c. of a standard commercial aluminum hydroxide cream was mixed with the diet of each dog daily. A carmen "marker" was given with the meal on the fourth day and again on the eighth day of each period. All feces passed from the first appearance of the first dose of carmen until the disappearance of the second dose were collected daily.

Each day the total feces passed by each dog were weighed and thoroughly mixed, and aliquots were taken for the fat and nitrogen determinations. In the

*From the Department of Physiology and Pharmacology, Northwestern University Medical School, Chicago, Ill.
Submitted September 23, 1937.

case of each dog all of the samples collected during each absorption period were pooled and the analyses were made on the composite samples. The samples for the fat determinations were preserved in alcohol; the samples for the nitrogen determinations were suspended in sulphuric acid as recommended by Peters and Van Slyke (3). Nitrogen determinations were made according to the Kjeldahl method; fat determinations according to a modification of Saxon's method (3). All determinations were made in duplicate.

RESULTS

In vitro experiments: The activity of the pancreatin was unaltered by the presence of the aluminum hydroxide cream.

In vivo experiments: It will be seen by consulting Table I, that the addition of aluminum hydroxide to the diet effected only the bulk of the feces. The differences in the nitrogen and fat content of the feces between the two absorption periods are all well within normal physiological variations. In fact, the constancy between the two periods and between the different dogs is striking. The bulk of the feces was increased by the addition of aluminum hydroxide cream in all of the dogs.

DISCUSSION

The dose of aluminum hydroxide cream administered in this study was comparable to the larger doses usually recommended clinically. The fact that it was administered in a single dose with the daily meal rather than in small divided doses should enhance the value of the results obtained. If gastro-intestinal enzymes were going to be inactivated as a result of adsorption, with a consequent disturbance in diges-

tion, the large single dose would be more apt to cause a disturbance than small divided doses. Although the system of demarkating absorption periods by the inclusion in the diet of inert materials which color the feces is not particularly sensitive, the difference between the two periods in the bulk of the feces is probably significant. The aluminum hydroxide itself, being largely unabsorbed, would contribute to the increased bulk, although in the case of dogs number 1 and 2 the increase was greater than could be accounted for on this basis. Aluminum hydroxide cream contains about 5% solid aluminum hydroxide. Therefore, during the 5 day period a total of only about 20 grams of dry material was added to the diet. The difference in weight in excess of that attributable to the solid aluminum hydroxide, is probably due to an increase in the water content of the feces resulting from the presence of the aluminum hydroxide.

SUMMARY

Since aluminum hydroxide is employed extensively as an enzyme adsorbent, it appeared possible that when administered orally it might interfere with digestion by adsorbing gastro-intestinal enzymes. Experiments conducted to test this hypothesis showed that relatively large doses of aluminum hydroxide cream did not alter the nitrogen or fat content of the feces of three normal dogs on a standard diet. This confirmed preliminary *in vitro* findings.

The History of the Development of the Stomach Tube With Some Notes on the Duodenal Tube*

By

JULIUS FRIEDENWALD, M.D.

and

SAMUEL MORRISON, M.D.

THE introduction of instruments of precision with their constantly changing additions and improvements frequently represent important stages in the development of a specialty in medicine. One need only refer to such instruments as the ophthalmoscope, laryngoscope, stethoscope, proctoscope, cystoscope and others as proof of this fact. Thus the stomach tube from the earliest times in its primitive form, to the present day with its many modifications and increasing possibilities has continuously played a peculiarly important role in the advancement of gastro-enterology.

Even previous to the discovery of the primitive tube, various practices were indulged in by the Romans to induce vomiting at the completion of a banquet in order to prevent the after effects of an overloaded stomach as well as to give place again for another

meal. At times emetics were employed but these seemed too uncertain in their results, and unpleasant as well. However, it was soon realized that it was only necessary to apply the finger to the throat to accomplish the same result. To escape the ill effects of these procedures Emperor Claudius and his guests were accustomed to allow the throat to be irritated with the "pinna" or vomiting feather at the completion of a banquet.

The celebrated medical historian Oribasius of the fourth century, A. D. fully described the methods employed in producing emesis at that time. Swinging the individual in a suspended bed was practiced until an artificial sea-sickness was produced. He likewise recommended as a substitute for the use of the finger, eight to ten goose feathers dipped in iris oil or cypress oil applied to the throat to induce vomiting. He also described an instrument consisting of a long feather

*Abstracted from Bulletin of the Institute of the History of Medicine, Volume IV, No. 6, June, 1935.

glove-finger, ten to twelve inches in length, of which the lower two-thirds are to be filled with wood fibre while the upper third is to remain empty to receive the directing finger of the physician. The digital vomitorium was to be lubricated with the oils already referred to and introduced into the esophagus. This instrument was considered by Leube as the most primitive type of stomach sound.

Avicenna in his writings in the 11th Century had also advised the use of a similar apparatus for the evacuation of the stomach. In his work on poisonings, Hieronymus Mercurialis (16th Century) recommended the application of the *lorum vomitorium* to produce emesis. This instrument had especially been lauded by Scribonius Largus in conditions of opium poisonings. It dates as far back as the first Century. The *lorum vomitorium*, a poorly described instrument, consisted, according to Leube, of a leather strap treated with some nauseating tannic acid-containing substance which produced emesis when introduced into the esophagus due to its obnoxious taste.

The three methods described, namely, the pinna, digital vomitorium and *lorum vomitorium*, had as a common purpose the evacuation of the contents of the stomach.

A further step toward the development of the more modern tube was made possible as the result of the introduction of apparatus intended not only for emptying the stomach of its contents but also for removal of foreign bodies from the esophagus or forcing them into the stomach. The oldest instruments utilized for this purpose were short perforated metallic tubes so constructed as to clasp foreign bodies such as fish bones and thus to extract them. Leube cites Guilielmus Fabricius Hildanus whose great skill was recognized in removing foreign bodies from the esophagus with a perforated tube to which a small sponge was attached at its lower end. An advance was made by Hieronymus Fabricius ab Aquapendente in advocating the propulsion of foreign bodies into the stomach when there was no possibility of their extraction by mouth. He also devised an instrument for artificial feeding. This was accomplished through a silver tube covered with sheep's intestine to be utilized for patients affected with difficulties in deglutition. Thus as early as the 16th and 17th Centuries a new method of artificial alimentation was devised and a new principle established which has gradually led to the further development of the stomach tube and to its present day modifications.

Toward the middle of the 17th Century a new application of the tube made its appearance in Europe and was heralded as a marvelous therapeutic measure. It was variously termed stomach cleanser or brush, or "magenkratzer or magenraumer." This instrument was devised so as to apply treatment directly to the interior of the stomach. The stomach brush consisted of a long smooth flexible arched whalebone two to three feet in length tipped with an ivory button to which a tuft of silk cord, horse hair or linen was firmly attached. The instrument was passed down the esophagus into the stomach and applied as a cleansing apparatus. The remarkable success attained by means of this instrument spread rapidly through Europe and many reports concerning its use were published in England, France, Norway and Germany.

This method of treatment finally developed into an

actual form of so-called "Cure"; the instrument being kept in a church or convent and treatment practiced there under great secrecy.

Leube narrates the following interesting account of a Russian statesman upon whom the stomach brush was used: A Statesman who had returned from Russia and who had been in bad health due to the abuse of alcohol as well as from over-fatigue was advised by the King to enter a convent for treatment. The inmates of the convent were in remarkably good health, notwithstanding their ages; among them a priest of 115 years who was still able to read and write without the use of glasses. The statesman seemed greatly impressed by the sight of such healthy individuals and was encouraged to undertake treatment. After four weeks of treatment, under the usual medication, no relief was obtained. The monks then decided to undertake the "secret cure" which they had been accustomed to practice upon themselves. However, after arranging for the fee, the patient was required under oath to swear never to reveal the "Arcanum," the method which was to be undertaken to restore him to health. The "Arcanum" was none other than the stomach brush and treatment was instituted following certain preparations. Although the patient seemed extremely distressed by the treatment and squirmed, spat out and vomited and begged to have the treatment discontinued, he was nevertheless forced to drink water and the brush was again applied until the stomach was entirely cleansed. This was undertaken in the morning and was continued at 24 hour periods for eight days. At the end of this time, the patient was quite able to continue on his journey in good health and in good spirits. Finally the secrecy with which this method of treatment was surrounded disappeared and its use was generally advised even for healthy individuals as a prophylactic measure with the object of attaining a long life and as a curative measure for all stomach troubles. The stomach brush was now manufactured in various places and was very commonly used by patients.

The poor results attained from this form of treatment in some instances and the fatalities that occurred especially in certain cases of carcinoma of the stomach gradually led to its disuse, and the instrument in the form of whale bone-sound tipped with a sponge was continued to be utilized only for the treatment of esophageal diseases and especially in obstructive affections. The famous case of Thomas Willis is interesting. His patient had difficulty in swallowing which gradually increased to such a degree that he was no longer able to swallow food. Death seemed imminent. Willis prepared an esophageal sound and the patient was given food which was thrust down the esophagus by means of this instrument. He received treatment in this manner for 16 years. Abercrombie later employed a silver esophageal sound with an oval knob at its tip for this purpose with great success. The problem which had not been satisfactorily solved up to this time and still confronted the physicians of this period was that of artificial feeding as well as the possibility of introducing remedies into the stomach when deglutition was impeded and likewise when the contents of the stomach required complete and prompt removal than was possible with emetics. This could only be accomplished with a sound of tubular form and of sufficient length as to extend into the stomach.

Hieronymus Capiwakeus and Fabricius ab Aquapendente were among the first to attempt to apply this form of treatment. Capiwakeus employed a tube with an animal bladder attached at its upper end containing a nutritive fluid which was expressed into the stomach. Fabricius ab Aquapendente introduced a small silver tube covered with lamb's intestine through the nose into the esophagus for purposes of artificial feeding.

A further development of significance was achieved when Van Helmont in 1646 discovered a method of manufacturing flexible catheters of leather which naturally could be made of considerably greater length and by Boerhaave (1668 to 1738) who suggested the use of a flexible stomach tube in cases of poisoning in individuals unable to swallow antidotes.

On March 21, 1776, John Hunter read a paper on "Proposals for the Recovery of Persons Apparently Drowned" in which he advised the use of "a syringe with a hollow bougie or flexible catheter of sufficient length to go into the stomach and convey stimulating matter into it without affecting the lungs."

Again 17 years later (1793) he published a paper read September 21, 1790, on "A Case of Paralysis of the Muscles of Deglutition, Cured by an Artificial Mode of Conveying Food and Medicines into the Stomach" in which he reported the case of John S., a patient of 50 years of age who had suffered with a paralysis of the muscles of deglutition which deprived him of the power of swallowing. Many forms of treatment were given without success and the administration of food and medication was advised by Hunter through a hollow flexible tube passed into his stomach. This was undertaken by him and given twice daily. The paralysis gradually disappeared.

In his Inaugural Thesis, Alexander Monroe, Jr., in 1797, suggested the use of the tube and syringe in cases of poisoning for the extraction of the poison from the stomach and for the introduction of food into the stomach in cases of dysphagia in human beings. He likewise pointed out that his father as early as 1767 had employed a flexible tube to remove fermenting fluids and gases from the stomach of cattle affected with esophageal spasm causing great distention and in whom vomiting was impossible.

In France both Renault and Dupuytren followed in 1803 with the suggestion for the employment of a flexible tube of sufficient length to reach the stomach connected with a syringe to aspirate the stomach in case of poisoning.

The credit for the introduction of the stomach tube into American Medicine is due to Philip S. Physick, Professor of Surgery in the University of Pennsylvania. Physick published his paper in 1812, entitled "Account of the New Mode of Extracting Poisonous Substances from the Stomach."

He declares that he employed the tube in washing the stomach of twins three months old who had accidentally been given an overdose of laudanum by their mother. He employed a large flexible catheter for this purpose. It was passed into the stomach and a drachme of diluted ipecac was then injected with a syringe. He then withdrew the fluid contents of the stomach through the sprig and injected warm water, which was again withdrawn. As a result one of the children was saved, the other died. Physick states that the idea of washing out the stomach with a syringe and tube in cases in which quantities of laudanum or other

poisons had been swallowed occurred to him at least twelve years before and he had constantly for many years recommended it in his lectures. In the year of 1809 his nephew, Dr. Dorsey, practiced lavage in a case, but the patient had swallowed the poison twelve hours before he was called, so that he did not succeed in saving life.

Of interest in this connection is a letter published by Physick in the same volume of *The Eclectic Repository* in which he states "I am happy in having called the attention of the profession to a mode of treatment not before used in this country, at least within my knowledge; but I have now an act of justice to perform, in ascribing the merit of the invention to Doctor Alexander Monroe, Jr., of Edinburgh, who published it in his inaugural thesis, in A. D. 1797. Of this circumstance I was entirely ignorant when I sent you my paper, and probably should still have remained so, had it not been mentioned in his book of *Morbid Anatomy*, a work which has but very lately come into my hands." Physick's priority as to the discovery of the stomach tube was apparently vigorously contested in this country. However, the controversy was by no means limited to this country but was even more vigorous and raging in England where contention ran high as Jukes, Bush, Evans and Reed, each claimed priority for the discovery about the same time.

As a further development in the chain of events a new instrument for the evacuation of the stomach was demonstrated by Mr. Reed of Hosmoden Lane, Kent, to Sir Astley Cooper and interested physicians at Guys Hospital on November 21, 1823. "Mr. Reed was in the theatre during the whole of the time and superintended the use of the instrument; on quitting he received the unanimous applause of those present. Sir Astley Cooper, just after the experiment had been tried, looking at what had been removed from the stomach, said that the instrument would do well for an alderman after a city feast."

The important improvement in the Reed instrument was in the special syringe, so constructed with two valves, that the need of removing the syringe in the process of gastric lavage could be avoided.

About the same time Weiss, an instrument manufacturer, developed and patented a new type of pump for the following purposes: (1) for emptying the stomach of poisons. (2) for removing water in drowning before applying artificial respiration, (3) for giving enemata.

The apparatus was widely used especially in Germany and many references are made to it in the German and English literature. There are always difficulties encountered in any attempt to establish the validity of priority in medicine as the development of a discovery is often so gradual and frequently enveloped in a series of events gathered from many sources, that it may become impossible to name any single individual who should receive the entire credit. This is especially so regarding the discovery of the stomach tube.

If we weigh the evidence in evaluating the priority in regard to the discovery of the stomach tube, it is quite clear that Boerhaave was the first to suggest the use of a flexible tube to be passed into the stomach as a method of treatment but there is no evidence that he ever employed it for this purpose. In 1776, however, John Hunter suggested the use of the stomach tube and in 1790 reported its use as a method of ali-

mentation in a case of paralysis of the muscles of deglutition. Renault and Dupuytren in 1803 published the description of a tube which they had perfected and Alexander Monro, Jr., in 1797, likewise suggested the use of a tube and syringe as a suitable means of extracting poison from the stomach; it does not appear, however, that any practical application of this apparatus was made in cases of poisoning or other conditions.

Philip Syng Physick advised lavage of the stomach with a tube and syringe in 1800, but his first publication only appeared in 1812. The reports of Jukes, Bush, Evans and Reed appeared later (1822) and therefore need not be considered in determining the matter of priority. Physick has been commonly acknowledged as the discoverer of the stomach tube especially in this country and one of us has formerly maintained this view and published a paper to this effect. His publication appeared in 1812, although he employed the tube in 1800. Further evidence, however, establishes the fact that the credit of this discovery of the stomach tube is due John Hunter.

In summary the conclusion is arrived at that John Hunter was the inventor of the stomach tube and was the first to make use of it in England; that the tube was first introduced into America by Physick and in France by Dupuytren and Renault. Following the rival claims of priority by Jukes, Bush, Reed and Evans and the appearance of the important publication of Alcock which followed in 1823, the tube was soon forgotten and was not generally employed until 1869, when Kussmaul, in his classic publication, suggested its use in the treatment of gastric dilatation.

Only a few publications of note appeared in the interim, that of Somervail in 1823, Arnott in 1829, both advising syphonage as a method of performing gastric lavage instead of by suction.

Kussmaul published his observations in 1869, and laid the foundation for an exact means of diagnosis in gastric disturbances. In this valuable paper Kussmaul describes difficulties encountered in the treatment of advanced forms of dilatation of the stomach due to stricture of the pylorus.

He remarks: "Very exceptionally was it possible to obtain any results in the treatment of this dreadful disease. As a rule it may hardly be possible even to expect an amelioration of the symptoms, and never possible to produce a cure."

Realizing the serious state as well as dire distress in a country girl of 20 years, in the wretched stage of vomiting the thought occurred to him that he might bring about relief by means of lavage of the stomach.

The introduction of the stomach tube, the pumping out, and washing were usually easy. Three liters of acid, dirty-gray, sarcina-containing fluid, with particles of food of all kinds undergoing softening and decomposition were withdrawn. This was first accomplished on July 22, 1867.

Although most enthusiastic over this new method of treatment, Kussmaul recognized its limitations. He realized that only when slight constriction of the pylorus existed was he able to obtain a cure in cases of dilatation of the stomach by lavage. In malignant stenosis of the pylorus and in cases of cicatricial contraction relief only could be afforded, and not cure. He says: "Naturally, it is impossible to expect a cure of a dilated stomach by means of lavage when the pyloric orifice is narrowed to such an extent that it

will hardly admit even as much as a goose quill." It is here that Kussmaul points out the possibility, that surgery would at some future day bring relief to these cases, and it is possible, as Fleiner suggests, that perhaps it may have been the inspiration of this remark that led Billroth at a not very distant date to attempt to cure intractable forms of gastric disease by surgical measures. Thus a new method of treatment, this epoch-making work of the great master Kussmaul, furnished the impetus for the study of gastric diseases according to modern scientific methods and led to the stomach-tube, not only as a new method of treatment but also of diagnosis.

Great credit is due Kussmaul who was the first to publish a definite method of treatment by means of gastric lavage for dilatation of the stomach and thus by creating renewed interest in the stomach tube established the beginning of modern methods of diagnosis and treatment of diseases of the stomach.

Since it was soon discovered that as the result of suction with the stomach tube trauma was often produced sufficient to withdraw bits of gastric mucosa from the stomach, syphonage, which had already been advised by Somervail and Arnott was again introduced by Ziemssen, Rosenthal, Rosenbach, Hodgen, Leube and Jurgensen.

Jurgensen likewise recommended a soft rubber tube and explained the method of introduction of the stomach tube, the position to be assumed by the patient as well as the method of practicing syphonage. This contribution must be classed as a distinct advance in the therapeutics of gastric diseases. Jurgensen utilized the rubber tube terminating in a perforated ivory ball. The bulb was guided by means of a wire stylet.

In order to more readily facilitate gastric lavage, double recurrent stomach tubes were now constructed by both Auerbach and Ploss. However, these were soon found impractical due to their large size and Hemmeter later developed a more useful tube of this type. It was after but an interval of five years, that Ewald and Oser introduced the soft rubber tube independently of each other which was to be passed without the aid of a mandurin. Ewald demonstrated, by chance, that if a rubber tube was sufficiently firm it could be introduced without difficulty. In a patient who had swallowed prussic acid with suicidal intent and who was brought to Frerich's Clinic, evacuation of the stomach had to be accomplished immediately. A stiff tube was not at hand and Ewald proceeded at once to remove a piece of rubber gas tubing, rounded off the sharp edge and cut out two eyelets. The tube was oiled and although the patient was unconscious he succeeded in passing the tube into the stomach.

Ewald and Oser were therefore the first to demonstrate that the soft rubber tube could be easily introduced into the stomach without the aid of a mandurin. While Kussmaul drew attention to the therapeutic value of the stomach tube, it remained for Leube in 1871 to point to the value of the stomach-tube as a diagnostic measure and also to emphasize the fact that it is impossible to arrive at a proper conclusion concerning the nature of gastric conditions without the use of this instrument.

Twelve years later (1883), Leube established his test meal as a means of determining the state of motor sufficiency of the stomach, concluding that a normal

stomach should be empty seven hours after the ingestion of a meal of soup, broth, steak and bread. This test of Leube's is recognized today as a most valuable means of determining variations in the motor function of the stomach. Leube also at this time analyzed the gastric secretion obtained through the stomach tube, by utilizing mechanical influences as for instance from the irritation produced by the prolonged use of the tube; by chemical influences, the ingestion of soda-water; and by thermic stimulation in swallowing ice-water. Riegel (1881) showed the difficulties encountered in obtaining gastric juice by stimulating the gastric secretion by means of ice water, according to the method of Leube, as but minimal quantities are thus obtained. He therefore advised the withdrawal of the gastric contents through the tube after his well known test dinner of soup, beefsteak, bread and mashed potatoes and also established the fact that the most favorable time for removal is at the height of digestion. He demonstrated here, too, that the absence of hydrochloric acid is a usual occurrence in cancer of the stomach even though this acid is at times absent in other conditions.

In their classical work on the "Physiology and Pathology of Digestion" (1885-1886) Ewald and Boas presented their experiments regarding the appearance of free hydrochloric acid and lactic acid in the stomach contents obtained through the tube and also drew attention to other important factors connected with the chemistry of gastric digestion. Ewald here fully described his test breakfast and presented its advantages as well as its importance in the diagnosis of gastric disease. The expression method of obtaining gastric juice is also described and was adopted as the simplest method of obtaining this secretion.

A further significant advance was made by the introduction of duodenal intubation, the possibilities of which are still in their infancy and are constantly widening. The first attempt at recovering duodenal secretion was undertaken by Boas in 1889, who was occasionally able to obtain duodenal contents by introducing the stomach tube in the fasting state following massage of the right upper abdomen. Boldyreff could likewise at times obtain this secretion by administering a fatty meal after which regurgitation of bile and duodenal contents would occur into the stomach.

Hemmeter was the first to actually attempt instrumental intubation of the duodenum though Turck had previously claimed to have succeeded in accomplishing this by means of his so-called "gyromele" which was primarily intended to outline the boundaries of the stomach by the aid of palpation over the abdominal area. Hemmeter passed a balloon into the stomach which was then inflated; following this a rubber tube was inserted over a groove on the upper surface of the balloon and was thus guided into the duodenum. His method, however, proved to be difficult and impractical.

It was not until 1909 that the duodenal tube of the present day type was introduced independently by both Einhorn and Gross. The tube was afterward modified by Rehfuss and others but these simply represent variations of the original Einhorn model. All consist of small soft tubes with tips so weighted as to rapidly pass into the duodenum. A modification of importance is the tube introduced by Levin in 1921, consisting of a smooth catheter entirely of rubber without the addition of a metal tip. It has the great

advantage in that it can be inserted both through the nostril as well as by mouth.

In the introduction of the duodenal tube another new era in the advancement both as to diagnosis and treatment in gastro-enterology was inaugurated.

While duodenal intubation was at first employed only for purposes of securing duodenal secretion it was soon recommended for duodenal and intestinal lavage. A further advance was made when Lyon in 1917 instituted his method of non-surgical biliary drainage by means of the duodenal tube with a solution of magnesium sulphate. This procedure is now successfully practiced both as a diagnostic as well as a therapeutic measure. Fractional gastric analyses so commonly utilized nowadays have likewise been made possible by means of the duodenal tube.

Duodenal intubation is now recognized as an extremely valuable measure in nourishing patients affected with certain digestive disorders associated with nausea or persistent vomiting. It has also been found very useful in the treatment of certain forms of peptic ulcer.

The duodenal tube is now largely employed following surgical procedures for purposes of aspiration of gastric and intestinal contents and for introducing fluids and nourishment into the digestive tract, for overcoming persistent vomiting and distention and is likewise a valuable measure in such conditions as gastric dilatation, ileus and localized peritonitis.

Continuous suction can be practiced through the tube and has been especially helpful in special types of intestinal obstruction as well as an aid following operative procedures for intestinal obstruction. The literature pertaining to duodenal intubation has become extensive and innumerable publications have appeared during the past years describing many important developments related to the digestive processes, in health as well as in disease, in which this tube has played a significant role. It would be beyond the confines of this paper, however, to attempt to supply even an outline of this extensive literature. Among the important contributors in this field other than those already referred to are Jutte, Palefski, Simon, Soper, Buckstein, Smithies, Ward, White and Paine and Wangenstein.

One cannot dismiss this historical sketch without a brief word regarding another type of tube through the introduction of which important diagnostic information regarding disturbances of the esophagus and stomach has been obtained, namely, the esophagoscope and gastroscope.

Kussmaul in 1868 was the first to attempt gastroscopy. He employed a rigid tube which he was able to insert into the stomach, but could not visualize this organ satisfactorily. Miculicz was the originator of the modern instrument. He was enabled by means of this instrument which was constructed somewhat on the model of the cystoscope to actually visualize the interior of the stomach.

In 1895, Rosenheim developed a new type of gastroscope which was further improved by Rewidzoff in 1897 and still further by Kelling. Chevalier Jackson modified this instrument which was further improved by Sussman.

On account of the difficulties encountered in manipulating these instruments successfully, gastroscopy was abandoned until 1922 when Schindler developed

his new instrument. This was, however, difficult to insert due to its rigidity and not until 1932 did he announce his newly constructed flexible tube which can be inserted without great difficulty or danger and by means of which an exceedingly satisfactory view of the stomach can be obtained. The development of esophagocopy has been greatly aided by the instruments devised by Killian, Hill, Jackson, Einhorn and others. It has enabled the gastro-enterologist to visualize all portions of the esophagus and thus has been of great value as a method of diagnosis and has likewise materially assisted in direct treatment as in the removal of foreign bodies, the direct application of remedies as well as in the removal of specimens for microscopic examination.

And thus we conclude a chapter in the history of

the stomach tube from the earliest times, beginning with the pinna and stomach brush to the present day tube with its modern improvements and many sided accomplishments.

The development of the tube into its present form portrays in a large measure the great advance made in our knowledge of digestive diseases. The interesting papers of Major and of Paine also bear this out.

As in other specialties in medicine, instruments of precision have often played a major role in their development, so too in gastro-enterology, the tube has assumed a similar role. It is possible that in the future as in the past, it will continue to lead the way to still further achievements in our knowledge of digestive diseases.

The Therapeutic Application of Acidophilus Milk in Constipation of Children*

By

LEO F. RETTGER, Ph.D., LOUIS WEINSTEIN, Ph.D.,
MAXWELL BOGIN, M.D.
and
JAMES E. WEISS, Ph.D.
NEW HAVEN, CONNECTICUT

THE very early recognition of constipation is attested to by the frequent references to the purge in ancient medicine. Various systems of classification of constipation have been proposed. For a discussion of this phase of the subject the reader is referred to a recent publication from this laboratory.[†] Bayliss and Starling (1899) and Cannon (1902) were apparently among the first to study the movements of the intestine. By the use of the X-ray administration of bismuth, and other devices, there has been established an elaborate mechanism which involves the normal rhythmic segmentation, peristalsis of the small intestine, the haustral movements, antiperistalsis and slow and rapid colonic waves in the large intestine. A disturbance of this mechanism must be regarded as an important factor in intestinal stasis, or the reverse of this condition.

The type of food ingested may greatly influence the frequency of evacuation of the intestine. Thus, a diet containing an appreciable amount of fiber is necessary before any regularity of evacuation can be accomplished. This has again been shown by the recent researches of Cowgill and Anderson (1932), and Cowgill and Sullivan (1933). Diets having very low fiber content, that is, so-called "low-residue" diets, lead to intestinal stasis. Again, during starvation, the bowel evacuation may not occur for periods of weeks. In determining the cause of constipation in any case, it is of utmost importance to take into consideration the nature of the subject's diet, including adequacy of the

vitamin content. It has been shown by some investigators that vitamin B complex, for example, plays an important role in the regulation of intestinal movement.

Diet is of special importance in its relation to intestinal evacuation in infants, since minor deviations from the proper regimen very frequently lead to quite severe intestinal disturbances. Nurslings are often constipated because of a low total solid intake in the diet. Frequently inadequate amounts of breast milk result in constipation. Similar problems present themselves in artificially fed infants. A striking example of constipation due to inadequate amounts of food is that of hypertrophic pyloric stenosis and pylorospasm where obstruction (functional or organic) of a severe type interferes with the passing of food from the stomach into the intestinal tract. Artificially fed infants are subject to some degree of constipation when the carbohydrate or fat content of the formula is deficient in amount. This accounts for the frequent use of malt sugar preparations in infant diets. On the other hand, over-feeding may result in excessive intake of protein and fat, which leads to a bulky residue of calcium soaps, which in itself causes constipation. As simple a factor as inadequate fluid intake may result in constipation in infants, although this cause of stasis is more frequently observed in older children and adults.

Mechanical factors also play a very important rôle in controlling the normal functioning of the bowel. In dealing with infants one is confronted all too frequently with constipation of mechanical origin. The relatively long large intestine of the infant, with its resultant large "omega" loop, and the sharp turns so often found in the sigmoid region, may offer obstruction to the fecal stream and predispose to constipation.

†The Journal of Pediatrics and the Therapeutic Application. Rettger, L. F., Weinstein, W., Bogin, M., and Weiss, J. E. Yale University Press, 1933.
Received for publication, June 27, 1933.

Hirschsprung's disease is an outstanding example of the effect of mechanical ineptitude in constipation. Other mechanical factors, such as congenital bands, may cause obstruction, and in older children post-infectious peritoneal bands or adhesions may result in varying degrees of stenosis of the intestinal lumen. More rarely, mechanical pressure upon the intestine may be due to neoplastic masses or to an enlarged or displaced viscus as, for example, the spleen, kidney or uterus. Interference due to enteroptosis occurs more frequently in older children than in infants, but volvulus and intussusception must be considered in constipation in infants.

Conditions which are essentially systemic in nature may cause constipation by an indirect effect on the intestinal tract. Thus, the atonic state of the abdominal and intestinal musculature in rickets in infancy predisposes to constipation. Similarly, intestinal stasis is also a frequent finding in cases of cretinism and in various nervous and mental disturbances.

Mention should be made also of the constipation ascribed to faulty habit. Not infrequently a child is too busily engaged in play to heed the normal desire for defecation, with resultant retention and consequent dehydration of the fecal mass. Injudicious parental management may result in situations of emotional stress, so that a child, endowed with sufficient negativism, and sensing the veritable obsession of the parent to constipation in childhood, may wilfully retain the feces.

In 1922, Rettger and Cheplin first recommended the use of acidophilus milk in constipation in adults. In 1933, Weinstein, Weiss, Rettger and Levy, and in 1935, Rettger, Levy, Weinstein and Weiss reported favorable results with acidophilus milk in the treatment of a large number of cases of constipation in adults. No attempts were made to treat this disorder in children, but it seemed that, in view of the fact that children are as a rule more reactive to various influences, acidophilus milk should be of much value in the treatment of constipation in childhood. With this in mind, the investigation reported here was undertaken.

METHODS

Children ranging in age from 10 months to thirteen years were included in this investigation. The authors were fully aware of the pitfalls into which one may easily slip in attempting to determine the cause of constipation. Efforts were made to eliminate mechanical, dietary, systemic, nervous and certain other causes of the disorder. Each child was observed for a period of at least three weeks before treatment with the acidophilus milk was begun. During this observational period, attempts were made to make the diet as nearly correct as possible nutritionally. In cases where there appeared to be an indication of mechanical stasis, X-ray pictures were taken following barium enemas. Attempts were also made to enlist the aid of the mothers of the children in trying to develop proper habits.

If, at the end of the period of preliminary observation there was no marked improvement in the constipation, the children were given one pint of acidophilus milk daily. In instances where infants were still on milk-containing formulas, the acidophilus milk was substituted for the sweet milk, all of the other ingredients in the formula being left as they were. The regular feeding schedule was not interrupted or

changed in any manner. For the older children the acidophilus milk was added to the diet in place of one pint of the sweet milk which most of the children were taking daily. No changes were made in the diets of the older children after the treatment with acidophilus milk was begun.

Stool examinations for *L. acidophilus* were made weekly in every instance, according to the technic previously described by Weinstein, Weiss, Rettger and Levy (1933). At least two stool cultures were made in each case before treatment was started. None of the subjects harbored demonstrable *L. acidophilus* in the intestine before treatment. All of the children were given the acidophilus milk for a period of at least twelve weeks. If, after withdrawal of the cultured milk from the diet, there was no recurrence of the constipation no further treatment was given; when, however, there was a return of the complaint the subject was again treated for a period of twelve weeks, after an intervening "rest" period of from two to four weeks. This alternate milk feeding and milk exclusion regimen, first definitely instituted by Weinstein et al (1933), was carried out until there was no return of the constipation for a period of at least twelve to sixteen weeks after cessation of treatment. In instances where only one feeding period was required, the children were under observation for at least six months after withdrawal of the cultured milk from the diet. The results were recorded as positive for the individual cases when there was no recurrence of the constipation during this period.

RESULTS

The acidophilus milk treatment was carried to completion in 27 children suffering from constipation, 22 females and 5 males. Ten other children all under three years of age were also treated, but for various reasons, such as difficulties experienced in administering the milk, were dropped from the investigation before the treatment had been carried on for four weeks. In a few instances the mothers complained of the milk being regurgitated soon after being taken. In these cases there was apparently some degree of intolerance for the acidophilus milk. No instances of marked distaste for the milk, or of vomiting after taking it, were observed in any of the children that were over four years of age.

Of the 27 children in which the treatment was carried to completion, 22 reacted favorably to the milk, 3 failed entirely to respond, and 2 gave results which were irregular and of a doubtful nature. Of the 22 children who reacted favorably 14 became so-called "implanters," that is, they carried the *L. acidophilus* organism in large numbers in their intestine for at least sixteen to twenty weeks after cessation of treatment. Eighteen of the responsive cases were treated for only one period of twelve weeks, while the remaining 4, together with the 2 doubtful cases, were first given the milk for one period of twelve weeks, then allowed a "rest" period of four weeks, at the end of which they again took the milk for twelve weeks. In the last-named cases the constipation returned during the first two weeks after cessation of treatment. After the conclusion of the second treatment period 4 of these subjects remained free from constipation during a period of at least six months. The other two still gave a doubtful reaction.

Owing to the unduly large amount of space required for full case histories of all of the subjects which were treated with acidophilus milk, descriptions of only one of the positive and one of the negative cases are presented here.

Case 1. J. S., male, age 10 months. Mother reported that the child had been constipated since birth. Certain corrections were made in the dietary before acidophilus treatment was begun, but without any beneficial effect. Following a preliminary observation period of four weeks, acidophilus milk was substituted for the plain milk in the daily diet. No improvement in the bowel condition was noted during the first two weeks of treatment, and *L. acidophilus* could not be detected in the stools. The mother had been instructed to give the child an enema of physiological salt solution when natural evacuation did not occur. In the third week the mother reported that the child had moved its bowels several times without the use of the enema. At the end of the third week *L. acidophilus* was present in the feces to the extent of about 25 per cent of the total viable flora. During the next nine weeks there were at least one or two normal stools daily, and the *L. acidophilus* content of the intestine varied between 60 and 95 per cent. Treatment with the milk was discontinued at the end of this twelve week period.

Within two weeks the constipation returned with its former severity, and no aciduric bacilli could be detected in the stool cultures. Acidophilus milk treatment was resumed at the end of the fourth week following its discontinuance. Within a week there was unmistakable improvement in the patient, and by the end of the second week the mother reported the child as having at least two natural movements daily. Stool examinations revealed an acidophilus count of 90 per cent of the total number of viable intestinal bacteria. The treatment was again continued for a total of twelve weeks, during which time there was no return of the constipation, and the *L. acidophilus* content of the colon remained high. At the end of this second acidophilus milk feeding period the milk was again omitted from the diet. Subsequent observation over a period of six months revealed no return of the constipation, and stool examinations showed a high *L. acidophilus* content, in spite of the fact that no acidophilus milk was being administered at any time during this entire period. The case was considered, therefore, as having reacted positively, and as having become an "implanter." When the child was seen again, one year after cessation of the last milk treatment, the mother reported that there had been no recurrence of the constipation. No stool examination was made at this time.

Case 2. A. G., male, age 8 years. The mother reported that this child had been constipated for four years. Attempts were made to correct the diet and to develop proper habits in this patient, without success. The various known causes for constipation in children were eliminated. No *L. acidophilus* was demonstrable in the stools during the observation period. The patient was given one pint of acidophilus milk daily. There was no relief from the constipation in the first four weeks of treatment. The lactobacillus count of the feces varied between 10 and 50 per cent of the total viable organisms during this period. Since no relief had been obtained, the amount of milk ingested daily was increased to one quart. Observation for a period of six more weeks showed no relief from the constipation. *L. acidophilus* at no time constituted more than 50 per cent of the intestinal organisms during this period. At the end of ten weeks of unsuccessful treatment the case was released.

DISCUSSION AND SUMMARY

Twenty-seven children ranging in age from ten months to thirteen years were carried through full treatment with acidophilus milk, for constipation.

Twenty-two of the group were completely relieved of intestinal stasis soon after the beginning of treatment; in this group there was no recurrence of the constipation for a period of at least four to six months after withdrawal of the acidophilus milk from the daily diet. Fourteen of the successfully treated individuals were classed as "implanters," since they continued to harbor *L. acidophilus* in the intestine for at least four months without the use of the cultured milk. In three of the children there was no relief from constipation even after treatment was continued for comparatively long periods. Two individuals gave doubtful responses, showing beneficial effects at one time and none at another. These reversals in bowel condition could not be correlated with any changes in the individual bacterial flora.

We wish to stress again the care which must be taken in experiments of the type reported here, to eliminate as far as possible all of the common causes of constipation in infants and older children. It is possible that in some of the cases which are included in this report a common cause of constipation may have been overlooked. It is our belief, however, that with a preliminary observation period of three to four weeks, with adjustment of the diet and elimination of all possible mechanical factors, most of the cases treated with acidophilus milk were suffering from constipation of unknown origin.

Milk to which a definite amount of lactic acid has been added has been prescribed by various pediatricians for constipation and other intestinal disturbances in children. Some persons may attempt to explain the favorable results obtained in the cases reported here as being due to the mere feeding of acidified milk. Evidence that the acid in acidophilus milk does not play a major part in the beneficial effects obtained in the treatment of constipation in adults has been presented by Kopeloff (1926). A similar conclusion was arrived at by the Orla-Jensens and Winther (1935-36). In the experiments reported here definite correlations could be established in almost every instance between the degree of relief from the constipation and the concentration of *L. acidophilus* in the lower intestine. When there were few or no aciduric organisms in the feces there were no indications of relief from constipation; conversely, when *L. acidophilus* constituted a large majority of the intestinal organisms, the patient experienced marked or complete relief from the constipation. Further evidence that the beneficial results were due largely to a change in the intestinal flora appears to be given support by the fact that a number of the children were free from intestinal symptoms long after acidophilus milk had been withdrawn from the diet. Stool examination showed that these individuals harbored *L. acidophilus* in the intestine, and most of them in large numbers.

Acidophilus milk is a wholesome food, in addition to being an effective agent in altering the intestinal flora. In view of the very fine curd which it possesses and the consequent ease of digestibility, it should be far superior even to sweet milk in the feeding of infants suffering from intestinal disturbances. The curd of acidophilus milk may be assumed to be of even finer consistency than that of artificially acidified milk, because the acid is formed slowly in the former and there is a continuous and slow precipitation of the protein of the milk. In using acidophilus milk in place

of ordinary sweet milk in the artificial feeding of infants, several facts must be borne in mind. First, that the prevailing brand of market acidophilus milk does not contain the same amount of fat as ordinary (market) sweet milk, and second, that part of the lactose has been removed by the organism. These facts must be taken into consideration in calculating the caloric value of the prescribed diet.

The authors are fully appreciative of the difficulties involved in a clinical experiment of this kind. The marked influence upon psychic factors of the administration of any substance, be it inert or potent, is always a problem in itself. We attempted to eliminate errors here by the use of preliminary periods during which enemata of saline solution were recommended, and in which the parent was informed that the disturbance was remediable, if regularity of bowel habit was encouraged, and the administration of fruits, vegetables and other standard laxative foods was carried out. Cases which responded to this manner of dietary correction were eliminated from the experiment.

The question of feasibility of administering soured milk to children and infants, raised by several parents at the beginning of the individual experiments, was not particularly provoking. Whereas, in a few instances we found it necessary to sweeten the milk slightly with chocolate syrup, a large majority of the children readily adapted themselves to the acidophilus milk, and in only one instance was its administration entirely abandoned because of the child's refusal to submit to it.

The question of cost raises a more difficult problem. Proper treatment of a case of true constipation necessitates prolonged and regular administration, and in the event of recurrence after cessation of treatment, a repetition of the 12 weeks' course. Our results followed close supervision of the cases over prolonged periods of time, with constant advice to the parents—a procedure of considerable expense in private practice. Against this cost one should weigh, however, what appears to be a permanent cure, at least in the cases in which the "implantation" of *L. acidophilus* results in complete relief of intractable constipation.

The authors wish to express their appreciation of the cooperative spirit of the personnel of the Bridgeport City Dispensary, which made available the clinical material for this experiment; and in particular to thank the Board of Directors, the Clinic Supervisor, the resident medical staff, and the nurses of the children's clinic.

Benign Ulcer of the Gall Bladder*

By

J. C. VAN RAVENSWAAY, M.D.
 BOONEVILLE, MISSOURI

BENIGN localized ulceration of the gall bladder, not the result of pressure necrosis from calculi, is apparently a rarely observed disease at the present time. It is interesting to note in a study of the medical literature that in the present era of widely advised and accepted gall bladder surgery only occasional cases have been reported (one case cross indexed as such in the past twelve years in the *Index Medicus* (1)). As evidence of the modern experience in this connection Graham (3) states in reference to cholecystitis "in our experience we have never seen complete loss of epithelium as a result of inflammation" and Boyd (2) says "it is remarkable how intact the epithelium may be in the worst gall bladders." Yet during the period of the early development of biliary tract surgery in which there was considerably more hesitance in the acceptance of this form of treatment, ulcer of the gall bladder was seen with sufficient frequency to warrant detailed discussion in certain of the publications of the time. The most thorough consideration of the subject found is in the monograph *Diseases of the Gall Bladder and Bile Ducts* (published in 1904) by Sir Arthur Mayo Robson (4) who points out that ulcers

may be found associated with stones, typhoid fever, cholera, and primary carcinoma of the gall bladder. As complications of ulceration he cites clinical examples of stricture, perforation, fistula, peritonitis, hemorrhage, septicaemia, and pyaemia. In his cases the complications were, in general, the precipitating factor which led to the discovery of the lesion. In the present case it was an incidental finding at operation.

CASE REPORT

A 32 year old white farm wife came for examination because of right upper quadrant pain of twelve months duration. There was a history of mumps and measles in childhood. In adolescence there were several episodes of moderately severe right lower quadrant pain with associated constipation but no nausea or vomiting. These lasted usually from one to two days and required bed rest. She was married at 22 and had a child at 24, following which she began to gain weight slowly. She was troubled with constipation since childhood and when seen was using laxatives two or three times weekly. During the twelve months before admission she had been bothered with attacks of right upper quadrant pain which came at irregular intervals, which were worse at night, not associated with nausea or vomiting, but which did radiate to the tip of the right shoulder blade.

*Van Ravenswaay Clinic.
 Submitted September 11, 1937.

Mucosal surface of gall bladder showing ulcer and stone in cystic duct.

Physical examination revealed a moderately obese white female in no acute distress. The pupils were equal and reacted normally to light. The nose and throat were negative. The heart and lungs revealed no abnormalities on physical and fluoroscopic examination. The blood pressure was 120/80. There was moderate right upper quadrant tenderness localized in the region of the gall bladder, and also right lower quadrant tenderness near McBurney's point. The pelvic and rectal examinations were negative and the reflexes not remarkable.

Laboratory examination revealed the following: Blood: red blood count 3,200,000, hemoglobin 65 per cent and white blood count 5600. Urine: acid, no albumin or sugar, sediment negative. A gastric analysis showed 16 degrees free acid 45 minutes after an Ewald meal.

X-ray: Films at 4 and 8 hours after the administration of intravenous dye showed no evidence of a gall bladder shadow. No opaque calculi were seen. A barium meal entered the stomach through a normal esophagus and the stomach and duodenal cap filled and emptied normally without evidence of intrinsic or extrinsic lesions.

A diagnosis of cholecystitis, probable cholelithiasis, and recurrent appendicitis was made and operation advised. Following a period of preoperative preparation cholecystectomy and appendectomy were done. Following this there has now been symptomatic relief for a year.

Pathological report (Dr. Thomas J. Kelly): Gross examination: The gall bladder is enlarged to two times the usual size, is greyish white in color, and has a definitely thickened wall. On the posterior surface of the fundus there is a deep ulcer involving the submucosa and muscularis. The ulcer has an indurated prominent edge and measures 1 centimeter in length, 0.5 centimeters in width, and 0.3 centimeters in depth. There is a single yellow mulberry shaped stone 0.5 centimeters in diameter in the mouth of the cystic duct. Microscopic examination: Sections through the wall of the gall bladder in the region of the ulcer reveal its edge to be composed of dense fibrous tissue while the base shows a mass of blood pigment, lymphocytes, and fibroblasts. Immediately below the base is an area of extensive fibrous tissue proliferation. A few eosinophils are noted. In the region of the ulcer the mucosa is absent. Sections through the remaining portion of the gall bladder reveal a slight diffuse eosinophilic infiltration with marked fibrous tissue proliferation.

DISCUSSION

Lesions of this type may occur more commonly than statistics would indicate. There is no apparent way of making a clinical diagnosis in the uncomplicated case. The definite demonstration of the lesion by X-ray would depend upon a chain of fortuitous circumstances. In the present case there was no concentration of the dye in the gall bladder. The etiological factors are also obscure. It seems unlikely that the single small stone is significant in this regard. If any analogy can be drawn from ulcers elsewhere in the gastro-intestinal tract this type of lesion is probably unimportant as a precancerous process. It is noteworthy, however, because of the non neoplastic complications detailed above which may follow its appearance.

CONCLUSION

A case of discrete benign ulcer of the gall bladder of obscure etiology is presented.

A Case of Peptic Esophagitis

By

FRANCES R. VANZANT, M.D., LOUIS DAILY, M.D.

and

JOHN ROBERTS PHILLIPS, M.D.

HOUSTON, TEXAS

BENIGN ulceration of the esophagus is rarely diagnosed because the clinical picture is not well defined; it usually produces no definite Roentgen-ray findings, and esophagoscopy examinations are not often made. The following case demonstrates the diagnostic difficulties seen in these cases, throws some light on etiology, and presents therapeutic problems which are as yet unsolved.

The patient, the wife of a physician, was aged 56 when first seen in November, 1934. She gave a life long story of intermittent indigestion of a vague type, the trouble gradually growing worse during the past two or three years. At one time a diagnosis of gastric ulcer had been made after an X-ray examination, and she was known to have diverticulosis of the colon. In addition there had been sick headaches associated with the gastric complaint.

In spite of the fact that her complaint in recent years had been of difficult and painful swallowing, several roentgenologists had carefully examined her stomach and intestines without ever looking at the esophagus until in August, 1934, at which time an X-ray examination disclosed obstruction of the lower portion of the esophagus. Esophagoscopy examination proved this to be due to an annular ulcer two inches above the cardia. The tissue removed by biopsy was diagnosed as inflammatory by two different laboratories.

At the time we first saw the patient, she was suffering intense paroxysms of pain following attempts to swallow either solids or liquids. The pain usually lasted from several hours to eighteen hours and was so intense that morphine was often given though with little benefit. At times chloroform anesthesia had been induced to give relief. The difficulty was intermittent, the severe paroxysms occurring about once a day. A bismuth and phenol mixture had helped to prevent pain and had enabled her to take sufficient liquids to avoid dehydration. Under the fluoroscope, the upper three-fourths of the esophagus was seen to be dilated. About two and one-half inches above the cardia there was a smooth, tight stricture which looked as though a string had been tied around the esophagus at this point. After a few minutes the barium mixture began to seep through the stricture, outlining a seemingly normal lower esophagus. Examination of the stomach showed many reverse peristaltic waves, rippling up over the stomach and carrying barium back up the esophagus as far as the point of stricture. An hour glass constriction was present in the lower one-third of the stomach, but no indication of ulceration was made out. Administration of three-eighths grain of ephedrine hypodermically caused a perceptible relaxation of the esophageal stricture and relief of pain.

For a few days, the patient seemed to derive considerable benefit from treatment consisting of three-eighths grain ephedrine and three-fourths grain amytal three times a day, alkaline powders and frequent bland feedings. Mucin was used at bed time with the idea of providing a coating for the ulcerated area.

Symptoms again became aggravated after a short time. Esophagoscopy examination was then made under general anesthesia. The dilated upper esophagus was found to contain a large amount of food debris, although food had been withheld for more than twenty-four hours. The mucosa was boggy with edema, just as one commonly sees it in cases of stasis due to malignant stricture. The area of stricture itself was seen to be ulcerated and bleeding. Several pieces of tissue were removed for examination and the whole area painted with silver nitrate. It was impossible to pass the dilator through the stricture. The specimens were examined at Mayo Clinic and found to be inflammatory tissue.

Following this, there was improvement for several weeks. One month later it was possible to pass an esophagoscope through the stricture and the annular ulceration was discovered to extend from the stricture practically down to the cardia. Relief of stasis had permitted the mucous membrane of the upper esophagus to return to a normal condition. Under the fluoroscope, spasm appeared to be much less marked but there was still considerable narrowing.

After a short interval of improvement, difficulty in swallowing again became aggravated. Larostidan therapy was tried. The drug was given intramuscularly in dosage of 5 c.c. on alternate days for six doses but there was no improvement and the treatment was discontinued.

Since the patient was now becoming dehydrated and she was unwilling to tolerate wearing a nasal tube for feeding, gastrostomy was performed on February 19, 1936, with the idea of subsequently being able to carry out retrograde dilation of the stricture. Exploration revealed no involvement around the cardia and no evidence of an infiltrating growth.

A formula was prepared consisting of milk, cream, egg, Karo syrup, yeast, cod liver oil, liver extract, pureed vegetables, and orange juice, and this mixture was administered through the gastrostomy at hourly intervals. The gastric content was tested before each feeding and sufficient alkali was given to entirely neutralize any free acid which appeared. Paroxysmal pain, however, still continued to occur and was associated with the regurgitation of food into the esophagus from which it was often vomited. Prompt relief of pain followed vomiting food or emptying the

stomach by aspiration. It was soon found that orange juice induced an attack of pain but no other ingredient of the formula could be incriminated.

Subsequently the stricture was dilated at weekly or bi-weekly intervals up to a size 40 French dilator. There was never complete freedom from the difficulty in swallowing, but after a few months, the gastrostomy was allowed to close.

In September, 1936, a cycle of migrainous headaches began and concomitantly there was increased trouble in the esophagus. Subsequently it was discovered that she had become allergic to eggs and milk. After the omission of these foods, her headaches and pain were relieved and the paroxysms were lessened.

Our interpretation of the sequence of events in this case is as follows:

The woman was an allergic individual with definite sensitization to milk, eggs, oranges, and possibly other foods. On ingesting these foods, she developed a functional disturbance of the gastro-intestinal tract, and as a part of this disturbance, she had reverse peristalsis in the stomach and up the esophagus as demonstrated repeatedly both under the fluoroscope and by observation during the time she was being fed through the gastrostomy. These waves carried acid gastric contents up into the esophagus where eventually a peptic esophagitis resulted. Spasm from irritation, together with narrowing from the scarring produced obstruction which became complete only when spasm was marked. Dilatation of the esophagus above the point of stricture resulted from the retention there of food and liquid. Stasis lead to edema and changes in the mucosa of the upper esophagus. The condition differs from the ulceration seen in cardiospasm in that the ulceration in this case lies distal, not proximal, to the obstruction.

In the treatment of this case, we have attempted to keep the organic stricture dilated and have tried futilely to keep the gastric contents neutralized in order to allow the ulceration to heal. The real need, however, is to stop the reverse peristalsis which is keeping the esophageal mucosa bathed with acid chyme and this has not been satisfactorily accomplished.

Jackson (1) reported twenty-one instances of ulcer in over 4000 cases subjected to esophagoscopy examination, an incidence of about 0.5%, and found scars of healed ulcers in an additional 1.7%. This incidence may be too low for esophagitis was found to be present in 7% of over 3000 cases which were examined at post mortem at the Mayo Clinic as reported by Butt and Vinson (2). Of these, 76.5% were acute and only 1.5% chronic lesions. They make the significant observation that 46% of all cases had vomited or had had gastric lavage prior to death. In other words there was evidence of retrograde flow of gastric content through the esophagus in about one-half of these cases with acute esophageal inflammation. Jackson also considers gastric reflux to be a characteristic of such cases.

There are many causes for back-flow into the esophagus; i. e. post-operative nausea, hour glass stomach, peptic ulceration of stomach or duodenum with pylorospasm, pyloric obstruction, etc. In our case, we believe the reflux was on an allergic basis.

Preplacing *B. Coli* by *B. Paratyphosus B.* in Large Intestines in Guinea Pigs*

By

DOROTHY K. O'CONNOR, LLOYD ARNOLD

and

HERBERT E. McDANIELS

CHICAGO, ILLINOIS

THE purpose of the experiments was to determine if the normal *B. coli* flora of the large intestine of guinea pigs could be replaced by a pathogenic gram negative bacilli. All adult animals died from infections before the flora was altered, or they were definitely pathological due to acute infectious process and the presence of the pathologic bacteria was a part of this process. We were unable to adapt the *B. paratyphosus B.* strain used to the large intestines of adult guinea pigs.

Young guinea pigs, beginning with the first day after birth were fed living *B. paratyphosus B.* by mouth. Varying dosage was employed. It was found

that 0.05 c.c. of a twenty-four hour old broth culture of *B. paratyphosus B.* could be tolerated by these young animals. The suspension was administered in 0.1 c.c. saline by dropping on the back of the tongue and stimulating swallowing. A catheter introduced through the esophagus causes injury and systemic infections followed. Fourteen young guinea pigs were used for the catheter experiments in feeding 0.05 c.c. of a twenty-four hour old culture of *B. paratyphosus B.* Twelve died and the bacilli were cultured from internal organs (kidney, spleen, liver and heart's blood) after death.

Sixteen young guinea pigs were fed daily for forty-eight to sixty-three days with 0.05 c.c. *B. paratyphosus B.* by oral administration without using a catheter.

*Research Laboratories of the State Department of Public Health and the University of Illinois College of Medicine, Department of Bacteriology and Public Health.
Received August 25, 1937

All of these survived. These animals grew in the normal manner; no evidence of infection was present at any time.

Fecal examination showed a gradual increase in the *B. paratyphosus* B. Bacteriological studies showed the *B. coli* to be present occasionally and then only one or two colonies. The *B. paratyphosus* B. was the predominant bacteria on Endo's media. This persisted for six months after termination of feeding in eleven of the sixteen animals. Five animals showed a gradual increase in the *B. coli* at the expense of the *B. paratyphosus* B. The latter was always present, but was not the predominant member on Endo plate cultures. No bacteriophage against *B. paratyphosus* B. could be isolated from the feces of these animals after repeated trials.

Blood was tested for agglutinins immediately after the feeding of the *B. paratyphosus* B. was stopped, and again four and six months later. Four animals gave positive agglutination titers—two in dilutions of 1:160 and two in dilutions of 1:80, all others remained negative.

We wished to see if these animals were protected against intraperitoneal injection of *B. paratyphosus*

B. One-half, one and two c.c. of a twenty-four hour old broth culture of B. paratyphosus B. were injected intraperitoneally into control animals. Two c.c. were lethal within forty-eight hours, half of those receiving one c.c. died within seventy-two hours, none receiving 0.5 c.c. died. The fifteen surviving guinea pigs, (one animal was accidentally killed) now approximately eight months old, were injected intraperitoneally, five in each set with 0.5, 1.0 and 2.0 c.c. of a twenty-four hour old broth culture. All died within three hours with evidence of hypersensitiveness. Some were clearly anaphylactic and died within a few minutes. This was an unforeseen and unexpected result and terminated our experiment.

B. paratyphosus B. fed to young guinea pigs in small doses daily for several weeks becomes a part of the large intestinal flora of these animals. This bacillus replaces to a great extent the *B. coli* in the feces. Only four of sixteen animals harboring *B. paratyphosus* B. as a part of their intestinal flora showed serum agglutinins against this antigen. All of these animals however, were hypersensitive to intraperitoneal injections of *B. paratyphosus* B.

The Nutritional Value of Soybeans

By

A. A. HORVATH†
NEWARK, DELAWARE

INTRODUCTION

SOYBEANS are one of the few basic food materials which have survived the severe test of milleniums on a large scale natural experiment, involving today nearly one-half of the world's population, and are endorsed by modern science as well.

In the Orient soybean curd (tofu) has been in daily use since times immemorial, and is called "the meat without the bones," as it serves as a food rich in protein.* Soybean curd is obtained from soybean milk** by the action (on heating) of a precipitating agent, such as the mother liquid obtained in the manufacture of salt from sea water, or of plaster of Paris (50). Fresh soybean curd contains in the average 8% protein, 3% fat, and 1.5% carbohydrates. Smoked soybean curd contains 17% protein, and frozen soybean curd up to 58% (50). The digestibility of fresh soybean curd is 95% for the protein and 99% for the carbohydrates (84).

It is believed by some individuals that soybean milk could be introduced into the daily diet of the American people, forgetting that the United States have a highly developed Dairy Industry, and that soybean milk does not suit the American palate. Soybean milk has received much attention in the medical profession where its use is being

recommended for medicinal purposes, a field which seems to be very promising† (28, 60, 63).

What is known in this country as "soybean milk powder" is mostly nothing but a finely ground soya flour, or a blend of some kind of powder made from soybeans with minerals, sugar or cereal, and cod liver oil. It is a dry mix, in which the "soybean powder" is in some instances a solvent extracted soya flour, and in others a soybean product of very poor taste, prepared by a "wet process," where ample rancidization had every chance to incur. Publications on "soybean milk" in infant nutrition in the American literature are actually dealing with "dry mixes" (38, 94, 95, 107) containing soybean flour. The nutritive properties of soybean-egg powder as a substitute for cow's milk in the infant dietary have been studied in China (112, 91, 92, 93).

COMPOSITION AND PROPERTIES

As an economic source of valuable and wholesome dietary elements the soybean probably has no peer. The recently published statement by the Food Research Division, U. S. Dept. of Agri. (9), reads as follows:

"Soybean flour is a concentrated, wholesome, nourishing, and economical food. It is rich in

in the stomach soybean milk gives a much finer flocculent precipitate than cow's milk. The ingestion of soybean milk results in a feeblor secretion of gastric juice, the period of secretion is also shorter. The period of stay in the stomach of the finely flocculent precipitate of the soybean milk is shorter than that of the casein-fat coagulum of cow's milk. The peristaltic motion of the stomach is less after the ingestion of soybean milk and more coordinated than in the case of cow's milk, as shown by X-ray investigation (114). According to other investigators (35) soybean milk curdles at a lower acidity than cow's milk. However, the same period of time is required for curdling.

†Chemist, Agricultural Experiment Station.

*The low basal metabolism of the orientals was to a certain extent attributed to their being vegetarians, and the basal metabolism was accepted as a measure of efficiency of a nation until recent studies showed the basal metabolism of the Maya Indians to be about five per cent above that of the white race (101).

**Soybean milk contains from 2.7% to 4.2% of protein, about 1.5% of fat, and 2% of carbohydrates. It is manufactured in the Orient in a way similar to our almond milk (50). The nutritive properties of soybean milk have been studied chiefly in China (111).
Submitted October 20, 1937.

protein, not only in quantity, but also in quality. It is rich in fat, in minerals and in most of the known vitamins. It is a cheap source of protein, fat, minerals and energy. It is alkaline in reaction."

The composition of soybeans is dependent on the variety as well as on climate and soil conditions. The oil content may fall below 14% or may reach over 21%, while the protein may range from 30% to 50%. The average composition of U. S. grown soybeans† is: Moisture, 8%; ash, 4.6%; fiber, 3.5%; protein, 40%; oil, 18.7% (9).

American grown soybeans* were found to contain a total of from 2% to 3.82% of phosphatides (calculated as lecithin) (55), the larger part of the total being cephalin, and the balance chiefly lecithin (82). Nearly two-thirds of the soya phosphatides are bound in the seed to the protein, presumably to its Arginine fraction (43). The soya phosphatides are also invariably bound to a di- or polysaccharide (44).

Soybeans contain up to 1.9 per cent of Phytin (25). The phytic acid, which is soluble in ethyl alcohol, may partly be responsible for the higher phosphatide figures as calculated from alcohol-extractable phosphorus. The principal distinguishing characteristics of soybean lecithins are the low proportion of saturated fatty acid containing a larger carbon chain than C_{18} , and the presence of linolenic acid (67). Cephalin from soybeans shows no marked difference from the one isolated from animal sources (67).

The presence of phosphatides in soybeans may have some special physiological value because phospholipoids are constituents of all the body cells, the nervous tissue being particularly rich in phosphatides.

Soybean oil contains the following acids: Linolenic, 2.2%; linoleic, 49.3%; oleic, 32.0%; palmitic, 6.5%; stearic, 4.2%; arachidic, 0.7%; lignoceric, 0.1% (11). The digestibility of soybean oil by man was shown to be from 95% to 100% for daily doses of 100 gms. (50). Soybean oil was shown to induce the organism of rats to an unusual amount of activity (89), which phenomenon may be explained by the peculiar electrical behavior of soybean oil as shown by the Dalliacqua test.**

The odor of the crude soybean oil is considered to be due to the presence of methyl-n-nonyl ketone (100).

Refined soybean oil compares favorably with other edible oils. Nearly 90% of the total soybean oil production of this country goes into the edible channel.

Refined soybean oil is deprived of the phosphatides as well as of vitamins A and E (45). Crude expeller oil as well as solvent extracted oil contain from 1% to 3% of phosphatides.

Solvent extracted soybean oil (by benzene) contains free sitosterol esters and sitosterol-d-glycosid. Commercial soybean phosphatides contain up to 2.8% of this glycosid (56).

The Nitrogen-free extract of the soybean consists of (108): Galactan, 4.86%; Pentosan, 4.91%; Organic Acids (as citric), 1.41%; Sucrose, 3.31%; Raffinose, 1.13%; starch, 0.50%; Dextrin, 3.14%; Waxes, color principles, tannins, etc. (by diff.), 8.60%. Immature

soybeans, as well as the easy cooking varieties contain a higher percentage of starch. According to a more recent analysis (65), shelled soybeans contain only traces of starch, no dextrin, 5.26% sucrose, no reducing soluble carbohydrates, 5.60% stachyose, 4.83% Arabin, 6.18% Galactan, and 1.63% Cellulose. Only the sucrose and one-fourth of the stachyose have to be considered as glucose forming substances.

For cooked soybeans, the utilization of carbohydrates by man is from 81.4% to 89.9% (81). Only one-half of this figure was recently obtained (3) on rats by investigators who used raw solvent extracted soybean meal from unshelled beans. This emphasizes the importance of cooking.

"The soybean is the richest in protein of all known foods except dried egg white. Even such concentrated animal foods as dried beef and cheese contain less protein than the average soybeans" (9). Nearly all of the protein matter of the soybean consists of a globulin "glycinin"† with which is associated a small amount of legumelin and proteose (87). The isoelectric point of glycinin is a pH of 5.0 (33). Glycinin is readily soluble in NaCl solutions, and is precipitated by dialysis or by dilution (86). When soybean meal is treated with water, upwards of 16% of glycinin is dissolved, but in this case the solution is doubtless due to the potassium phosphates contained in the seed (86).

During the process of commercial solvent extraction of soybeans by benzene the protein is denatured, presumably through deamination and hydration (43), and only a small part of it can be extracted by aqueous leachings (43). Treatment of the glycinin with NaOH solutions results in the splitting off of one-half of the Arginine (69) and the loss of nearly one-half of the cystine sulphur (in the form of H_2S) (85). One should therefore be cautious in interpreting the results of experiments on the nutritive value of "purified" soybean protein.

Glycinin contains: Glycine, 1.0%; Valine, 0.7%; Leucine, 8.5%; Proline, 3.8%; Phenylalanine, 3.9%; Tyrosine, 1.9%; Cystine,† 1.10%; Aspartic acid, 9.4%; Glutamic acid, 19.5%; Arginine, 8.10%; Histidine, 1.40%; Lysine, 9.1%; Tryptophane, 1.7%; Hydroxy-glutamic acid, 5.5% (87, 9). There exist marked differences in the cystine content of the glycinin from different varieties of soybeans. While the glycinin from the Illini variety contains only .74% of cystine, the glycinin from the Mammoth Yellow, the Virgini, the Haberlandt, the Manchou, and the Chiquita varieties contain .92, .95, .98, 1.45 and 1.46 per cent respectively (20).

The protein of the soybean was found to be adequate for promoting normal growth and "physiologically good"§ (22, 59, 88). The favorable findings were all obtained on cooked soybean protein, while raw soybean protein is of lower biological value (34), especially when it is fed with the hulls (80).

Numerous feedings experiments conducted in this country as well as abroad established beyond any doubt that for babies the soybean proteins are com-

†The Manchurian commercial soybeans contain an average of 8.5% moisture, 14% oil, 40% protein, 2% non-starch polysaccharides, and 1.5% ash (33).

‡The soybean meal (33) contains only about 16.45% of oil. The rest there was in the country about 6,000,000 acres under soybean cultivation.

**See also A. A. H. Smith: "Some chemical aspects of soybean oil" (March 1934, issue of "Oil and Soap").

†For its calculation from Nitrogen the factor 5.7 should be used instead of the customary 6.25.

‡The old assumption that glycinin contained sulfur in some complex other than cystine (85) was confirmed in more recent times by the discovery of 1.6% methionine in glycinin (91).

§Efficiency of soybean protein in cystine has been reported by some authors (76, 101). Recently it has been found that cystine or its equivalent may exist in the raw protein of the soybean in a form which is not available to the animal (35). It appears that heating the soybean causes the cystine fraction of the protein to become available (35).

parable to cow's milk proteins (91, 92, 93, 94, 95, 107, 112).

The digestibility of soybean protein in cooked beans fluctuates between 60% and 80%*, depending upon the thoroughness of cooking and the fineness of the particles (purec) (39, 50, 84).

Pepsin was found to have a higher digestive effect on glycinin as compared with soybean protein denatured by benzene extraction, while pancreatin showed a higher digestive power on the denatured protein (43). The protein of soybean milk is more rapidly hydrolyzed by pepsin than that of cow milk, the reverse is true with trypsin. When acted upon by both enzymes, the protein of cow milk is shown to be the more completely digested. The optimal pH values for the enzymic proteolysis of these two varieties of milk as substrates are almost identical. The protein of soybean milk and the protein of cow milk were found to have a digestibility of 84.9% and 86.6% respectively (4). The "apparent" coefficient of digestibility of soybean protein by white rats in "experimental" expeller oil meal amounted to 85% (34)** The digestibility of protein in "processed" edible soya flour is still higher.

As early as 1915 it was discovered by an American physician (98) that soybean flour is of great value for feeding children, is readily digested, and is particularly useful as a food in summer diarrheas. This was confirmed by German as well as French physicians (12, 71, 90, 114) who recorded that on a soybean diet the intestinal flora turns *Gram*-positive.

It was discovered in recent times that *Lactobacillus Acidophilus*, when grown in a medium prepared from soybeans (with the addition of Lacto-Dextrin), develops much more rapidly than in cow's milk, maturing in ten hours, about half the time required for cow's milk cultures. The individual bacteria are fully fifty per cent larger, and far more robust in appearance. The number of bacteria per c.c. exceeds the count of milk culture by fifty to one hundred per cent. Soy acidophilus cultures are also much longer lived, retaining their vitality for many weeks, and appear to preserve the natural characteristics of the organism, so that it more readily adopts itself to the anaerobic life in the human intestine† (60).

Curative experiments on rats rendered anemic on an exclusive diet of cow's milk demonstrate that soybeans are effective in the regeneration of hemoglobin (2). When in dogs blood plasma proteins are depleted by bleeding, plant and grain proteins are quite well utilized to form new plasma protein, but soybean meal

probably should be rated at the head of this list. It is utilized with unexpected promptness and favors the production of albumin in contrast to other plant proteins which distinctly favor globulin production. The potency ratio of soybean meal is between 5. and 7. which places it in a class with liver (74).

The soybean contains the following mineral constituents (29) (in per cent of dry substance): Potassium, 2.095%; Sodium, .380%; Calcium, .230%; Magnesium, .244%; Sulphur, .444%; Chlorine, .025%; Phosphorus, .649%.‡ Excess of total base over total acid = 31.24 c.c. of *n* solution (per 100 gms.). According to other authors, the excess base is as high as 37.89 c.c. (71), and even 42.00 (61).

It has been shown that while alkalization of a human being by the administration of sodium salts (bicarbonate or citrate) is followed by a retention of water amounting to about one kilo and greater perspiration during exercise, the alkalization by the corresponding potassium salts results in a one kilo loss of water by the body and a marked reduction in perspiration during exercise (24). The deficiency of the soybean ash in sodium and the large excess of potassium places the soybean in the latter class of alkalizing agents.

Recent experimental studies on humans showed that when the alkalization by a diet consisting of two-thirds of a pound of soya flour + milk + vegetables has begun one or two days before the test, the fatigue incurred in a well trained cyclist in 50 minutes as against a normal period of 36 minutes, and when the ergometer is set at a high resistance the period of fatigue inducement is extended to 33 minutes as against a normal of 19 minutes (24). Attempts to build up an adequate alkalosis by a liberal diet of potatoes, milk and other vegetables have failed (24).

Feeding soybeans to rabbits results in an increase in the inorganic phosphorus in the blood (42). The available figures of phosphorus and calcium metabolism in infants were obtained on solvent extraction soya flour, on which chemicals were acted upon during the process of manufacture, and to which minerals were added (107).

Of the enzymes, soybeans contain: Amylases and Diastases (17, 32, 108), Proteases§ (16). Lipases* (true lipases and esterases) (10, 51, 108), urease (110), uricase (79), oxidases and peroxidases (7, 50, 108). It has been recently reported (105) that while the lipase potency does not vary with the varieties of soybeans, the peroxidase varies from 7.56 to 88.02 units, and the urease from 26.86 to 60.76 units. The peroxidase of the soybean has found application in

*Higher figures were obtained where some soy sauce was used for seasoning the beans. Soy sauce is very popular in the Orient for use in cooking and as a relish or condiment to increase the flavor and palatability of the diet. In odor and taste it is not unlike a good quality of beef extract. It is prepared from a mixture of soybeans, wheat or barley, salt and water, by a long continued fermentation where *Aspergillus Orizae* plays a leading role, in co-operation with certain bacteria (84). Soy sauce contains an average of 19% NaCl, and from 1% to 8.5% of sugars (50). The cleavage products of soy sauce contain among other substances some histamine, to which is attributed the stimulating action of the sauce on the musculature of the stomach and intestines as well as an enhancing action on the absorption of foods by acting as a relaxing agent on the capillaries of the gastric and intestinal mucosa (11). It was also found that soy sauce contains substances which stimulate the saccharifying action of Taka-Diastase from 16 to 32 times, and the proteolytic action of pancreatine from 4 to 8 times (52). Soy sauce is therefore valuable as a seasoning agent and also as an ingredient of other table sauces (19); Worcestershire sauce consists of soy sauce, vinegar and spices.

**The temperatures given are lower than the ones actually used in commercial oil milling by the expeller method (6)

†The Soy Acidophilus milk, which the Dionne quintuplets take today, is given them to prevent the recurrence of the severe bowel infection which they suffered when four months old. They were relieved by the use of Soy Acidophilus milk after other measures had failed (62).

‡Whole soya flour contains: Total ash, 5.7%; Potassium, 1.860%; Sodium, .230%; Calcium, .300%; Magnesium, .380%; Phosphorus, .700%; Sulfur, .365%; Chlorine, .071% (9). According to another author (58) the P₂O₅ content amounts to 32.2% of the total ash. Soybeans contain 2 to 3 times as much ash as does wheat 4 times as much potassium and sodium, 5 times as much calcium 3 times as much magnesium 2 times as much phosphorus, about the same amount of sulfur, but only one-third as much chlorine. Soybeans are also richer than navy beans and lima beans in most mineral constituents (9). Soybeans contain appreciable amounts of iron and copper (2). It has been established that the iron in soybeans is "available" to over 60 per cent, being equal in this respect to beef and pork liver, superior to beef muscle, and twice superior to spinach and blood (95).

§Experimental feeding of raw soybeans (soaked over night in water) to rabbits resulted in some instances in lesions in the stomach which could be ascribed to the digestive effect of the proteolytic enzymes of the soybeans, as the organism possesses no corresponding antiferment (42).

*The soybean lipase from raw soybeans can be absorbed from the intestinal tract into the blood, and is capable of causing fat necrosis in animals (51).

the baking industry for the bleaching of dough (99, 113), and the urase for the leavening of bread in the presence of urea.

As early as 1917 it has been found that soybeans contained an adequate amount of the "water-soluble vitamin" and contained also "some of the essential fat-soluble vitamin" (antirachitic as well as anti-xerophthalmic) (88), which findings were corroborated in the same year by others (23). A recent quantitative estimation showed that soybeans contained three times as much B₁ but only two-thirds as much B₂ as does dried cow's milk (103). In 1925 it was demonstrated that a daily dose of one c.c. of solvent extracted soybean oil was sufficient to prevent as well as to cure rickets and xerophthalmia in young growing rats** (40). It is reported that there are higher concentrations of Vitamin A and B in the soybean embryo than in the endosperm (83). There is also no doubt that the Vitamin A content of the soybeans varies, depending upon the variety of the soybean and the degree of maturity. In 1925 the presence of Vitamin E in soybeans was established (22), which findings were confirmed recently by other investigators† (109).

In 1930 the discovery was reported that soybean feeding has an enhancing effect on the clotting of hen's blood (41). Later investigations (1935) showed it to be related to the oil fraction of certain seeds, and the term "Antihæmorrhagic Vitamin K" was proposed for the active principle (21). The addition of 2 per cent of soybean oil to an experimental diet provides an adequate level of Vitamin K for newly hatched chicks (53).

In 1936 a protective factor against nutritional encephalomalacia of chicks was discovered in the non-saponifiable fraction of certain edible oils, which are headed by soybean oil (31).

NUTRITIVE VALUE

In 1934 the nutritive value of green immature soybeans has been studied, and the following conclusions reached (75):

"As compared with most vegetables, they have unusually large amounts of protein, fat, calcium, phosphorus, and iron. Cooked immature soybeans proved to be a very good source of vitamins A, B and G, and a poor source of vitamin C."

Studies of one month duration on four human indi-

viduals kept on a mixed diet containing substantial quantities of boiled mature soybeans showed that the protein, fat and carbohydrates of the soybean were assimilated to an extent of 88%, 88% and 100% respectively as compared with those of meat and fish (70).

It has been established that the longevity of rats on a diet of ground raw soybeans is much shorter than on whole raw soybeans (13). This phenomenon is due to the rapid incurrence of rancidity in the crushed raw soybeans, enhanced by the peroxidase of the soybean seed, resulting in the destruction of vitamin A and E, and in the formation of toxic oxidation products from the oil, such as nonylaldehyde and dioxiacetone‡ (45, 106). Treatment with "active" ground soybeans destroys at least 99 per cent of the vitamin A present in cod liver oil (30), and the incorporation of the latter in feeds will therefore be rather harmful than beneficial (68). The destruction of vitamin A and the formation of toxic substances in feeds containing either ground raw soybeans or rancid soybean meal§ were greatly responsible for most of the poor results obtained which cast an undeserved shadow on the quality of soybean protein, on the vitamin A content of the bean, or on the calcium content of the soybean ash.

It is also necessary to take in consideration the fact that, in spite of being rich in calcium (0.25%),* the soybean contains an excess of fat over a favorable Ca/Fat ratio (48), and the diet has to be balanced accordingly.** Yet, some investigators who believed the soybean to be deficient in minerals were adding from 20 to 25% of butter fat to an experimental diet containing soybeans, and, of course, they had to counterbalance the ill effect of excess fat by the addition of 5 per cent of artificial salt mixture (88).

In order to prepare a soya flour of satisfactory keeping quality which is suitable for human consumption, it is essential to inactivate the peroxidases, oxidases and lipases of the soybean by an appropriate heat treatment (49), which also causes the methyl-nonyl ketone (100) to volatilize, leaving a flour of pleasant taste. Average data on three types of flour (of which only the high fat flours are actually "processed") are as follows (9): See Table on page 181.

One pound of processed whole soya flour (from shelled beans) has a fuel value of from 1980 to 2070 Calories (65).

In a recent authoritative publication† it is stated that "Soybeans and soybean flour may properly be considered as having protective food qualities, because they are rich in minerals, rich in high quality protein, rich in fat, and rich in vitamins, and hence serious thought should be given to their inclusion in the American diet."

*On the other hand there are experimental data (54) showing that soybeans have comparatively little Vitamin D value. The high phosphorus content of the soybeans, the large part of which is composed of phytates, might have been responsible in some instances in simulating Vitamin D action (115, 131). Attempts were made to correct the deficiency of various soybean flours in Vitamin D (in solvent extracted flour in Vitamin A as well) in baby foods through the incorporation of cod liver oil or egg yolk. The use of cod liver oil in blends with soya flour should be discouraged as the oil is subject to rapid rancidity in view of the large surface exposed to oxidation in the surface of the flour particles, resulting in the destruction of Vitamin A, D and E, in the formation of toxic aldehydes and ketones and in a rancid taste. (Such practice also encourages the use of inferior grades soya flour since its poor taste is veiled by the cod liver oil). Egg yolk is also subject to deterioration in blends with soya flour, and it adds, unnecessarily, oil and phosphates to soya flour which is already rich in these substances.

†An edible soybean oil, containing Vitamins A and E, as well as the phosphatides, can be prepared from refined edible whole soya flour (45). With the addition of irradiated ergosterol, such Vitamin D enriched soybean oil could be incorporated in our daily ration, and this action in many instances the necessity of having recourse to cod liver oil. While for human beings cod liver oil is fatal in large quantities, and cod liver is best avoided in animals, cod liver oil causes paralysis (due to degeneration of skeletal muscles, and incomplete atrophy of the heart muscle) on a synthetic diet containing cod liver oil (72).

‡Experiments showed that while young growing rats are capable of subsisting for 30 days without any vitamin A in the diet, they die in 8 days if given butter oxidized by exposure to ultraviolet rays, with the formation of peroxides and all the resulting oxidation products (106). The irradiation of milk and bread by ultraviolet rays should therefore be discouraged.

§The particles in hydraulic press and expeller meal have the disadvantage of being coated with an oil film which offers a large surface to oxidation.

¶Confirmed by feeding experiments on animals (44).

**Even a large amount of cod liver oil in a ration produces an entirely atrophic effect (74).

†By the Food Research Division, Bureau of Chemistry and Soils, U. S. Dept. of Agriculture (9).

Since the ash of the soybean is strongly alkaline† the incorporation of soya flour into a mixed diet counterbalances its acid components. On an alkaline diet the organism is spared the necessity of providing ammonia to neutralize the inorganic acids obtained

	High fat flours %	Press cake flours %	Solvent extracted flour*
Moisture	7.04	7.70	7.73
Ash	4.60	5.75	2.66
Fat	21.11	7.30	1.58

*On one commercial sample which it seems was subjected during the process of manufacture to treatment with chemicals

**Flours prepared from roasted beans as well as from beans that had been dipped in hot oil are especially low in K₂SO₄-soluble protein and in NaCl soluble protein

***Soybean flour is rich in Calcium (9) 'It is quite evident that soybean flour is one of the cheapest sources of Calcium' (9)

****One pound of soybean flour contains therefore as much lecithin as 4 to 6 eggs" (9)

*****C of N acid per 100 g sample

*****C of N/10 ammonia

from the food (37). Fundamental studies on "Protein Requirement and Mineral Metabolism," which were published in 1931 (14), established the following facts:

1. That the utilization of the food proteins depends, directly or indirectly, from the ratio inorganic bases/inorganic acids in the organism as well as in the food;
2. That a big excess of bases in the organism as well as in the food is a necessary precondition for an optimal utilization of protein;
3. That, therefore, a real minimum for protein requirement can be found only when there exists an excess of bases in the organism as well as in the food;
4. That with the increase of the excess of acids in the food as well as in the organism itself the nitrogen requirement of the organism mounts uninterruptedly until finally the physiological

impossibility of an immediate excretion of the by-products through the kidneys prevents a further rise and produces the illusion of a storage;

5. That in this way it is possible for the optimal figures of Voit to become under certain conditions the minimum figures.

The conclusion to be drawn from these findings is that the alkalinity of the soybean ash is a highly important factor for causing a saving in protein, and this is probably the main part of the explanation why experimental data showed that a human organism is able to store three times as much Nitrogen from a soybean food as from meat§ (96).

Soya flour does not act as a strong stimulant for gastric acidity, but is rather acid reducing, does not overburden the stomach, and does not affect the normal course of gastric motility. The digestion of soya protein goes remarkably rapidly, and the soya meal leaves the stomach mostly in 2½ to 3 hours, and in some instances even in 80 minutes (81).

The therapeutic uses of soybean preparations have been studied mostly in Germany (18, 114).

Soybean flour in any proportion up to 30% can be used with flour, white or whole wheat, not only for making bread but also for cake and other baked products. Bread made with 20% whole soya flour and 80% white flour contains a somewhat higher percentage of water and about 150% more ash and 40% more protein than white bread* (9).

Experiments conducted in 1921 by the U. S. Department of Agriculture (57) showed that bread made with a mixture of 25 parts of soybean flour and 75 parts of wheat flour contained a protein mixture and water soluble vitamins adequate for normal growth. A similar bread containing 15 parts of soybean flour and 85 parts of wheat flour likewise furnished adequate proteins and water soluble vitamins for normal growth. These mixtures of the soybean and wheat protein were found two or three times more efficient than the proteins from wheat alone. The results obtained by other authors (53) in Japan, when 10% soya flour was used to supplement corn or rice, were also good. In 1931 experimental studies conducted in Poland on the effect of soya—wheat and soya—rye bread on growth lead to the conclusion that a supplementary relation exists between the proteins of white wheat flour, or rye flour and soybean flour** (64).

In 1927, in Italy, studies on the nutritive value of a sole diet of soya bread† were conducted on six normal individuals, who received soya bread for periods of from 4 to 6 days (26). The average daily ration was 739 gms. of a 10% soya bread per capita, with a protein content of 97.3 gms., and 2,940 Calories. Two other normal individuals received for a period of five days a sole diet consisting of 831.5 gms. of a 20%

†The acidity or alkalinity of foods (in c.c. of N acid or alkali per one oz.) is (61):

Whole milk	0.5 (alk)
Soybean	12.0 (alk)
Wheat flour (pat)	2.7 (ac)
Bread (white)	2.0 (ac)
Beefsteak	3.0 (ac)
Eggs	3.1 (ac)

The high alkalinity of whole soya flour has made it a very effective remedy in the treatment of pyrexia in children, in eczema, and diabetes (12, 71). In cases of eczema due to idiosyncrasy to milk of animal origin soya flour has a double therapeutic value due to its high alkalinity coupled with the presence of glycine instead of the casein and lactalbumin.

§Performed on two individuals one given the meat and the other the soya diet

**A well baked soybean bread possesses an attractive crust a rich cream-yellow crumb, and has an agreeable aroma and taste. In other words it has appetite-appeal" (9).

†Some investigators explain this phenomenon mainly by the supplementary action of the soybean lysine and arginine on wheat flour

‡Baked from military whole wheat flour to which were added 10% or 20% of solvent extracted soybean flour. The shortage of fat was supplemented by giving with the bread from 25 to 30 gm. of butter per day

soya bread, containing 127.6 gms. of protein, and 3,273 Calories per capita per day. The utilization of the soya bread was:

	Total absorption from the 10% soya bread %	Total absorption from the 20% soya bread %
Dry substance	93.72	92.41
Calories	93.84	92.43
Nitrogenous substances	83.40	80.30
Fat	94.13	93.70
Carbohydrates	96.59	97.01
Mineral substances	68.60	62.53

While the assimilation of the 20% soya bread lies within the satisfactory limits for white bread, the 10% soya bread was found in appearance, digestibility and utilization equal to a bread from sole wheat of best quality, having the advantage of containing a higher percentage of nitrogenous substances (26). The general conclusions were that the soybean flour, when added to bread or other nutritive food preparations, is going to become a valuable supply of cheap protein for the alimentation of the people (26).

In 1928 complete metabolic experiments were conducted in Germany on ten normal individuals on the utilization of a sole diet of a 20% soybean bread* (from solvent extracted as well as from whole soya flour) with the following results (80):

	Utilization (In per cent)				
	Nitrogen	Carb.	Fiber	Ash	Calories
Bread containing 20% of solvent extracted soya flour	79.61	95.91	51.93	67.94	91.75
Bread containing 20% of processed whole soya flour†	80.40	98.58	55.22	76.07	94.06

The utilization of carbohydrates in 20% whole soya flour bread is superior even to the utilization of starch in white bread (80).

In 1927 another important metabolic experiment was conducted in Germany for five days on one individual who received a sole diet of 900 gms. of soya-rye bread* (containing 15.9% protein) plus coffee and butter (97). The results showed that the incorporated soya protein was extremely well digested (93%), did not cause any disturbances and was chiefly utilized for building and improving the body of the experi-

mental person, and the minerals were also, as normally, stored up in the body in corresponding amounts. The soya-rye bread did not show any irritating properties, and rather a lessening of these on the intestines as compared with rye bread. The addition of soya protein acted as if some animal protein was added. In five days the man gained 11.09 gms. of Nitrogen, corresponding to 69.41 gms. of protein or about 352 gms. of muscular meat. Besides, the soya protein did not produce any undesirable rise in the activity of the intestinal glands, which is a noticeable advantage. The authoritative conclusions of the experimenter were that the introduction of such a soya bread for human consumption should be recommended "since the enriched bread is excellent in its exterior, taste and utilization, since it keeps fresh for an extraordinary long time, and since the added soya protein is much better utilized than the proteins of the usual cereals" (97). The incorporation of soya flour in bread may help the baking industry in our country to recover the 20% decline in wheat consumption which occurred since 1904 (47).

Besides bread and bakery products** the other main outlets for soya flour are for the manufacture of crackers†, pancake flour, cocoa-malt mixest, baby foods, chocolate, puddings, ice cream powders, macaroni products, and sausages.§ The addition of soya flour renders these products more nutritious and palatable* (46, 49). The incorporation of over 3 per cent of soya flour into sausages is prevented in this country by the lack of a simple and accurate method for the determination of the percentage of soya flour for Governmental control purposes (66).

CONCLUSIONS

The 1935 recommendations of the Committee on Nutrition of the League of Nations emphasize that all possible steps should be taken to make food supplies, and especially protective foods, available at prices within the reach of all classes of the community. One answer to this recommendation is given in a recent publication from the Food Research Division of the U. S. Dept. of Agriculture (9), which reads as follows:

"The most expensive food constituents are minerals, vitamins, proteins, and fats. Soybean flour is rich in all these food constituents and yet relatively cheap. The moderate cost of soybean flour makes it possible for people of small incomes to obtain the maximum of these essential nutritional constituents required by the body which in the form of other foods might be beyond their reach."

*Such as coffee cake and doughnuts.

†Only solvent extracted soya flour gives a product that will keep indefinitely.

‡The cocoa-malt blend often sells a soya flour of poor quality.

§Mostly meat flours are being used today for sausages. Since sausages containing a substantial amount of soya flour can be sold at a reduced price, this may provide the packing industry of our country with a means of expanding the consumption of meat.

*Soya flour has also been recommended as an emulsifier for mayonnaise (27), and recently the whipping ability of soybean protein has been discovered (71).

Blood Diastase in Hepatic and Biliary Disease*

By

M. RACHMILEWITZ, M.D.
JERUSALEM, PALESTINE

ALTHOUGH the pancreas is held to be the chief site of formation of diastase it has been noted that after pancreatectomy a certain amount of diastase still remains in the blood, and has a definite tendency to return to normal levels (1, 2). Very small amounts also continue to appear in the urine. Consequently it is assumed that diastase may have its origin in other organs than the pancreas, particularly in the liver.

Whereas the diastase estimation in blood and urine has been widely accepted as useful means for investigation of pancreatic function, the fluctuations of this ferment in disorders of the liver are hardly known. In a brief publication, Somogyi (3) recently devised a new method for the determination of diastase in the blood, in which he reports that low values are found in patients with liver damage. The amount of sugar in the serum is determined, then 1 c.c. of serum is incubated for 30 minutes at 40° C. temperature with ordinary freshly prepared potato starch, sugar is again determined, and the difference between the first and second determination gives the activity of diastase present in the serum. Thus the quantity of the

tory results and enables quantitative evaluation of diastase. According to Somogyi and our own experience, this method is sufficiently sensitive to permit the determination of very small quantities and fluctuations in the amount of enzyme. The values obtained by us in normal fasting individuals and animals correspond to those found by Somogyi. They vary ordinarily between 80 and 100, as shown in Table I, which gives the results obtained in 15 normal individuals. The figures demonstrate that there is no parallelism between the blood sugar and diastase level.

Forty patients suffering from various liver diseases, 32 of them associated with jaundice, were examined. In some of them the diastase determinations have been repeated several times during the course of the illness. The total number of diastase estimations in this group amounts to 67. In many instances the bilirubin content of the blood has also been determined, as well as the diastase output in the urine, made by the Wohlge-muth method. The results are given in Tables II-VI. In 12 patients the blood diastase was found within normal limits, the rest (28 patients) showed a definite lowering, which we consider below 70. In the majority the blood diastase was much lower—less than 50.

The diminution of diastase did not parallel the blood sugar, which remained within the normal range in most instances; it also did not correspond to the severity of the jaundice at the onset of the disease. However, we could observe a gradual increase of the blood diastase together with the clinical improvement. Patient No. 4 (Table VI) may serve as an illustration of this observation. He was suffering from dermatitis exfoliativa, lasting several months with clinical signs of liver involvement, and a markedly enlarged liver. Three successive determinations at different intervals revealed complete absence of diastase in the blood. At this period the galactose test showed a slightly increased excretion of galactose in the urine (4.25 g.) and a negative Takata-Ara reaction of the serum. There was no jaundice during the entire period of illness. With the improvement of the dermatological and general condition, the blood diastase rose first to 22 and later to 43. A similar, but less severe case (No. 7, Table VI) also showed at first a marked lowering of diastase (29) which increased to 48 after clinical improvement began. The same was found in patients suffering from catarrhal jaundice who showed at the onset a lowering of blood diastase (Table II). In the instances of catarrhal jaundice with normal diastase values (Nos. 2, 5, 8, 11, 12, 14) the disease had a milder course and was of short duration. On the other hand, a gradual lowering of the value was observed in patients in whom a further aggravation of the disease had taken place. This group contains only two instances where the diastase was above normal, including case No. 2, Table III, who was suffering from repeated attacks of cholecystitis and cholangitis, with

jaundice, accompanied by fever. There was also a persistent steatorrhea, glossitis and a hyperchromic anemia, i.e. the symptom complex of sprue. At the onset of his illness (April 3, 1935) the blood diastase was normal (105). On September 15, 1935, when the above mentioned symptoms were more pronounced, the blood diastase was definitely raised (180), while the urine diastase was still normal (40 units). The second patient (No. 15, Table II) was admitted to the hospital with acute catarrhal jaundice. He complained of abdominal pain which was clinically and roentgenologically proved to be due to an old duodenal ulcer. While under observation, the pain became more intense and radiated to the back, fat was found in the stool, thus indicating involvement of the pancreas. The blood diastase which was first below normal (48)

rose suddenly to 256, subsequently dropped to 180 and then, with subsiding signs of pancreatitis, to 92. The increase of the diastase level in the blood, in spite of long standing liver injury, we ascribe to the pancreatic dysfunction, and the blood diastase in these two cases was the result of two conditions which influence the diastase level in an antagonistic manner. This question will be discussed later. In the six cases of atrophic cirrhosis of the liver (Table IV), three had normal diastase value (Nos. 1, 5, 6); one (No. 3) slightly reduced, and the other two (Nos. 2, 4) showed a marked lowering of the diastase with progress of the disease. The functions of the liver tend to remain normal in the type of hepatic disease exemplified by atrophic portal cirrhosis of which the pathological evolution is slow. The deviations are present when superimposed

hepatitis or terminal cholemia occurs. Accordingly, the blood diastase showed no variations from normal in the cases in which jaundice was absent and in which the mechanical obstruction of the portal circulation produced the outstanding symptoms. This agrees with the findings of the cholesterol partition of the blood obtained by E. Z. Epstein and E. B. Greenspan (4).

The following group comprises 26 patients suffer-

ing from various affections of the gall bladder (Tables VII and VIII). There were among them 7 patients with acute cholecystitis (Table VII). All of them except one had a normal diastase in the blood. The one with the low diastase level (No. 6) was a pregnant woman who was suffering from acute cholecystitis. Two successive determinations revealed practically the same result (36 and 32). The complicating pregnancy may account in this instance for the low blood diastase. Another patient (No. 2) showed at the onset of the acute cholecystitis a slight lowering of the blood diastase (58) which became at once normal (135) when the attack subsided. Of the 19 patients with chronic gall bladder disease (Table VIII) only 4 had normal diastase, the rest of them showed a definite lowering. Two patients with chronic inflammation of the colon accompanying the cholecystitis (Nos. 2 and 4) had the lowest figures. In the case of No. 2 an acute exacerbation of the colitis accompanied by fever caused a drop of diastase to 24 which rose gradually to 62 and 103 with the patient's improvement and the remission of the colitis.

As far as the presented data in non-obstructive biliary disease permit, we can assume that acute dis-

cases of the gall bladder have no effect on the liver, whereas chronic gall bladder disease produces a various degree of liver damage, manifested by lowering of the blood diastase in the majority of instances.

Of particular interest is a patient (R. Sh.—Table IX) suffering from repeated attacks of common duct stones and cholangitis in whom the blood and urine diastase fluctuations are particularly significant. The history of this patient is briefly as follows:

September, 1931. Cholecystectomy and removal of several stones after attacks of cholelithiasis, accompanied by fever and jaundice.

June, 1935. Second admission. For the last three weeks, pain in right upper quadrant radiating to the back and right shoulder. In the hospital frequent attacks of chills

and transient icterus. The blood diastase at the admission was normal, then with progressive symptoms and repeated attacks of cholangitis a tendency to become low.

September 1, 1935. Cholelithotomy. Four stones from the common duct removed.

September 9, 1935. After removal of the drain clay-colored stool, bile excreted through wound. Occlusion, probably inflammatory in origin, at the papilla Vateri is assumed.

September 16, 1935. A sudden rise of the blood diastase to 393 and 542—normal urine diastase.

September 18, 1935. Blood diastase normal (93). Large amounts (10,000 units) were found in the urine the same day and the following day. Gradually, however, the urinary diastase became normal.

January 1, 1936. Second cholelithotomy was performed, because of recurrent attacks of pain in the right upper

quadrant and signs again indicating occlusion of the common duct. Stones were again found and removed from the common duct. The patient made an uneventful recovery.

COMMENT

The present data justify the conclusion that blood diastase, determined by the method of Somogyi, is definitely lowered in liver damage produced by hepatic and biliary disease, particularly of long duration. It seems to us of particular importance that the improvement of the general condition of the patient, as well as of the liver function, is accompanied by a rise of the diastase level of the blood. On the other hand, progressive symptoms of the liver disease and further impairment of the liver function lead to further lowering of the blood diastase. In using the diastase estimation in the blood as an aid in the evaluation of liver function in diseases of the liver and biliary tract, repeated determinations during the course of the illness give an indication of the trend and are therefore of much more value than a single determination. We have been careful to avoid the term "liver function test" since there are numerous instances of elevated or lowered levels of blood diastase in other diseases, which cannot be definitely considered an expression of a disturbance of hepatic function.

The mechanism which leads to the depression or even disappearance of diastase from the blood in liver damage is not clear—and it lies outside the scope of this investigation. Zucker and his collaborators, who like Davis and Ross (5), have observed a lowering of serum amylase in animals after liver injury by chloroform, believe that this effect is through the pancreas. On the other hand, Crandall and Cherry (6) claim that in pancreatic lesions or ligation of the pancreatic ducts, it is not the condition of this organ that influences serum enzymes, but that secondary changes

in the liver control enzyme level in the blood in virtue of an alleged enzyme destroying power of the liver.

For clinical purposes the effect of the liver in depressing the diastase level of the blood must be considered in using diastase as a diagnostic procedure in diseases of the pancreas. We believe we have demonstrated this in the above mentioned instances where liver impairment was associated with involvement of the pancreas and pancreatic dysfunction. Whereas the latter leads to a rise of blood diastase, the accompanying liver damage will depress it. In an extensive study of diastase excretion in the urine in cases of jaundice, Milbourn (7) found high values in common duct stone but rarely in parenchymatous diseases of the liver. He noticed that the duration of the jaundice appears to be of considerable significance for the occurrence of increased or normal diastasuria in cases of jaundice due to common duct stone, increased diastasuria being commoner at the beginning of the jaundice. This is an indirect proof that with progressive liver injury the diastase diminishes even in those instances where the pancreas is responsible for its rise.

The present investigation confirms the observation made by other workers in this field that blood diastase determinations are of greater value and significance than urine diastase determinations.

CONCLUSIONS

1. The Somogyi method for diastase determination in the blood gives satisfactory and fairly constant results.
2. The blood diastase is lowered in liver damage produced by various parenchymatous diseases of the liver.
3. In using diastase determination as a diagnostic it is depressed in the majority of chronic conditions.
4. In diseases of the gall bladder the blood diastase

Quantitative Studies on a Case of Migraine*

By

RIVKAH FAINER, M.D.

HAIFA, PALESTINE

WITHIN recent years a number of reports have appeared concerning the problem of migraine. As a chief factor partial dysfunction of the sympathetic system has been suggested. Dean Clare, Héloïse Hough and H. G. Wolff, *Arch. Neurol. Psychiatry*, 35 (1936) obtained simultaneous records of the systemic arterial blood pressure and the cerebro-spinal fluid pressure inducing experimental headache by means of histamine with its vasodilatory action. Aubry, Thiodet and Ribère, *Compt. Rend. soc. biol.*, 122 (1936) have proved that the serum albumin-globulin ratio is above

Subject, R. F., female, aged 32, weight 56, 5 kg., height 158 cms. Clinically any other cause of headache had been excluded.

The basal metabolism has been determined by use of the Knipping apparatus, patient being held under basal conditions. A high carbohydrate diet was given previous to the fast in order to secure a glycogen store, as the patient has always proved to have a blood sugar level below the normal. Castor oil was administered on the evening preceding the fast and on the third day of fasting. The subject did not change her

normal and the departure from the normal is greater during the period of calm between attacks than during attacks themselves.

Our knowledge of the etiology of migraine is still obscure and it would lead us too far to discuss this matter.

The present research has been undertaken to study the metabolic changes in a case exhibiting all the classical features of typical migraine.

Experimental:

To minimize the influence of food and putrefaction products we studied the basal metabolism during the fast.

ordinary activity during the time of starvation. She took daily 3 cups of tea with sugar, about 12 gms. in all.

The determination of the carbon-dioxide combining power was also carried out under basal conditions. Blood was drawn without pressure from the vena cubitalis and centrifuged under paraffin oil in presence of sodium oxalate and fluoride. Plasma was used for the analysis. The CO₂ was estimated by means of a Van-Slyke closed manometric apparatus, the Van-Slyke-Sendroy tables being used for total CO₂ and expressed in volumes per cent.

The pH was measured by colorimetric method. Blood sugar was determined by the micro-method of Hage-

dorn-Jensen. For analysis of residual nitrogen the modified Bang micro-Kjeldahl method was applied. The serum calcium was examined by precipitation with ammonia-oxalate, centrifuging and titrating with a 0.01 normal solution of potassium permanganate.

The results of those analyses are given in Charts I, II and IV.

The respiratory CO₂ diminished gradually from day to day, whereas the amount of oxygen consumed showed some fluctuations, though there was generally a tendency towards decrease, the respiratory quotient remaining nearly constant until the fourth day.

The marked rise of the blood residual nitrogen may have been due to the cleavage of protein bodies. It is a well known fact that its amount is higher in starvation than in normal conditions. There is nearly no

change in the blood sugar level after one day fasting, its yield being increased about 23 per cent on the second day.

A close correlation between the amount of blood sugar and non-protein nitrogen was evident, the amount of both being nearly equal during the time of starvation.

It should be noted that the patient felt quite well during the first three days of the fast, as she was absolutely free of headache. On the fourth day an attack of migraine occurred, accompanied by nausea and vomiting. This attack was associated with a pronounced fall of the respiratory quotient and a striking drop of both blood sugar and residual nitrogen. A glance at Chart II will make it evident that no energy was at that time supplied by carbohydrates, as the store of blood sugar was nearly exhausted.

Further examinations made on the patient proved that severe attacks were always associated with a marked drop of blood sugar, even when blood was taken about two or three hours after meal.

We also studied the influence of drugs and a mixed diet on the metabolism of the above patient. The results are given in Chart III.

Other data are given in Chart IV. The amount of serum calcium is decreased between attacks, whereas there is a striking rise in the calcium level after a severe attack with vomiting.

The CO₂ combining power somewhat exceeded the normal limits. It was of interest to us to compare the

results obtained with another normal ease where an increased CO_2 power could have been expected. Blood of a healthy subject, vegetarian for more than twenty years has been therefore examined and the total CO_2 found still higher. The quantity of uric acid was re-

duced. Allantoin, identified as such by microscopic examination as well as by chemical test, has always been present in the urine in considerable amounts after severe attacks.

Our interest was aroused by the fact that the amount of reducing sugars of the blood has always proved to be below the normal value (65-78 mgs. per cent), even when the subject was previously kept for some time on a high carbohydrate diet. An increased sugar tolerance was therefore suggested. A test made has confirmed this suggestion. The results of the test are given in Chart IV.

SUMMARY

In the case of migraine studied, a decrease of reducing blood sugar, residual nitrogen, uric acid and calcium was found at times between attacks. The sugar tolerance is increased and the CO_2 combining power of the plasma was on the upper limits. During attacks a marked drop of the blood sugar was noted. Allantoin appeared in the urine after severe attacks, the blood serum calcium being about 28.5 per cent higher than at calm between attacks. The amount of blood sugar was not reduced during starvation, its value being higher than normal on the second day of fasting.

Further investigations are in process.

I wish to express my gratitude to Mr. Mose Wilbushovich, founder of the Scientific Research Laboratory, Haifa, who has enabled me to make this study, and to Miss Lea Olshansky for making the gaseous metabolism determinations.

Editorials

THE DIET OF PRIMITIVE AND ANCIENT MAN

PRIMITIVE man must have been a hunter. He chased and killed before he feasted. He collected seeds of wild grass, soaked them in water or mashed them between stones. Wild grasses grew in spots, primitive man ate only the seeds of these cereals, therefore he was fortunate to be in the right place at the right time and season to enjoy a wild wheat, barley, millet or rice meal. The food-accessory substances or vitamins in such seeds were of great health value to these folk. Growth, reproduction and maintenance were aided by ingesting the seeds of these cereals. Primitive man was primarily a meat eater. The pelts of animals he killed for food served as insulations during the cold weather. These were an ever moving folk, seeking shelter only when it was necessary for survival. Ventilation was of no concern to primitive man. The physical exertion coincident with the acquisition of food, insured a good appetite. He was not troubled with overweight.

Man very early acquired the ability to control some of the forces or factors in his environment. This reacted to his advantage. So long as he was a collector of wild seeds and a hunter of wild animals, he experienced considerable competition. The herbivorous animals fed upon wild grasses before, during and after the seeds ripened. Carnivorous animals were not only his competitors but his enemies. When man began to tame some wild herbivorous animals, he insured

himself a good food supply. When man began to plant the seeds of the wild grasses, he also reaped a harvest of food. He used the tame animal to increase his acreage of planting, to bear his heavy loads. He now had property. This was the beginning of an organized social system. He and his neighbor had something in common and they agreed to unite and protect their property.

Omitting a gradual development of man and his diet from early to modern times, we can think for a moment about how different our present environment is to that mentioned in the preceding paragraphs. During the last fifty or sixty years man has made rapid progress in controlling his environment. He has by physical, chemical and biological measures so changed the world in which he lives that only the outdoor air and weather conditions remain beyond his control. He can synthesize, concentrate, refine, refrigerate, and preserve his food. Rapid transportation allows him to have tropical, semi-tropical or arctic food during the whole year. His diet is no longer regulated by seasonal climatic conditions. He can live in houses constructed like incubators, temperature of the inside air can be regulated to suit his own sense of comfort. Ventilation becomes an important problem. These artificial changes in our environment have not been made during the span of one life time. It required many, many thousands of years for man to adapt himself to changes in environment during the

natural process of evolution. Some of these changes extending over centuries were much less drastic than the way we have artificially changed our environment during the last three decades.

From the primitive stone-throwing hunter and collector of seeds of wild cereals to the pastoral and to the agricultural forms of civilization was indeed a slow process. The acquisition of food was the big stimulus behind this movement. Diet has played a tremendous role in history of man. When he was able to accumulate enough food to satisfy his body needs and even store an excess in ease of necessity; then he had time to wonder why day followed night and why the moon changed in shape after a cyclic manner. With a leisure or land owning class of people emerging from such a civilization, we find records of some of the things they thought about. The great architectural monuments and the writings we now possess of Egypt, of ancient Greece, of Italy, of Assyria, of northern Africa and of north China were all produced by cultivators and consumers of wheat. The monuments and letters of southern India, of the Hindu-Chinese countries, of south China, of Java and of Sumatra were the products of rice-cultivating and a rice-consuming folk. The massive and extensive monuments of ancient Mexico and Peru have been left by corn cultivators and corn consumers. The hunting and pastoral people lead a wandering and nomadic life. The struggle for existence tended to develop a fierce and fighting type of man. The hunting folk attacked the herds of the pastoral people, the latter multiplied faster because of their better and more dependable food supply. The pastoral folk all through history and even at the present time lead a nomadic life and attack the agricultural people at each and every opportunity.

We find the ancient folk used the milk of their domesticated animals for food. It is interesting to note that they soured the milk before ingestion. Throughout the east soured milk is called "leben." The Egyptians boiled the milk of their buffalo, cow or goat, allowed it to cool to open air sun temperature and added some previously soured milk from the day before. The fermentation was rapid and was completed in about six hours. The technical procedure varied with the various people, but soured milk was extensively used in Egypt, Palestine, India, Arabia, Turkey, Balkan States, etc.

Grapes were cultivated by these ancient people to make wine and vinegar. Wine is an acidulated alcoholic beverage. Vinegar was widely used as a preservative for various kinds of fruits and other perishable foods. When viewed as a whole, that is when their total available food is taken into consideration, one cannot but be impressed with the acidified diet ingested by these ancient people living together in communities in the cradles of civilization.

We know that the Roman legions added some vinegar to their cup of water while marching and fighting in foreign countries. This was evidently the result of experience. We are told that this kept these soldiers from having pestilence and diseases common to the various countries they were invading and policing. A cup of water with a little vinegar added is a refreshing drink to a tired person. The Biblical reference to the placing of vinegar upon a sponge to Christ's lips during his crucifixion was a humane act on the part of the Roman soldiers. This is what they

were accustomed to doing to exhausted and wounded comrades. We are informed in the Book of Ruth that the reapers in the harvest fields refreshed themselves by dipping their bread in vinegar before eating it.

Some idea of an ancient feeding habit of man can be gained from the camel drivers on the deserts. These people allow the camel's milk to sour, then evaporate it to a solid consistency. This forms part of a camel drivers food while on the desert. He sits in the shadow east by his camel, adds water to a handful of this "soured milk powder" to suit his taste and thirst. The small shady spot in which he sits is cool in contrast to his previous hours in the hot sunshine. He slowly drinks his lunch in comfort.

Sir Austen Layard in recording his experiences in the desert some seventy-five years ago, states that the Bedouin's food consists of wheaten bread, a few wild herbs, such as asparagus, onions, garlic, some fresh butter, curds and sour milk. The milk of their sheep and goats was shaken into curds and was rarely or never drunk fresh. This author mentions that fresh milk was unwholesome when drunk in the hot desert climate and states that he can vouch for this from personal experience. The sour milk or leben was their principal food. He further states that the Bedouins enjoyed a freedom from sickness and possessed an extraordinary power in withstanding fatigue. Cholera and other diseases never were epidemic among these people. Smallpox was their greatest pestilence.

The acid-base equilibrium of the contents of the stomach and upper part of the small intestine is an important factor in maintaining health. Diet plays a role in the reaction of the contents of this part of the alimentary tract. The ingestion of acid-buffered food assists in the maintenance of an excess of acid over alkaline reacting substances in the stomach and upper half of the small intestine. This is particularly true if there is a deficiency in the acid secreting power of the stomach. The advantages of acid-buffered foods in infant feeding illustrates this principle.

The biological nature of the controlling mechanism of the bacterial flora of the intra-intestinal contents was summarized in a previous editorial (Amer. Jour. Dig. Dis. and Nutrit., 4:603, 1937). The feeding habits of ancient man were sound and scientific in view of our present state of knowledge.

Lloyd Arnold, Chicago, Ill.

A SUGGESTION AS TO THE MODE OF PUBLICATION OF THERAPEUTIC RESULTS

ONE of the everyday problems of editors of medical journals is what to do with papers reporting brilliant results in the treatment of disease with some new drug. Every student of therapeutics knows that every time a new drug catches the fancy of physicians or proves to be useful in one small field of disease, it is immediately tried out extensively for the relief of almost every known malady. Always, at the beginning, many laudatory articles are written, and then, after months or years, it becomes apparent that either the remedy had no value at all, or else it was useful in the treatment of only one or more closely related conditions.

Thus, a century ago, quinine, having been found wonderfully helpful in malarial fevers, was promptly

used in the treatment of all other fevers. From this success the idea grew that it must be a great tonic; hence, it soon was being used in the treatment of depressed states and anemias of all kinds. Today, the pharmacologist would probably say that its usefulness outside of the field of malaria is doubtful, and the better trained and the more thoughtful a physician is, the more likely he is to use the drug only for the treatment of malaria.

Similarly, some forty years ago creosote was thought to be an excellent remedy for tuberculosis; because of its reported success in this field, the drug was widely used for colds and coughs of all kinds, and later it was given as a tonic. Today, I doubt if one could find one expert in the treatment of tuberculosis who would think of giving it to his patients. With its horrible and long-lasting taste, it is a miserable drug to give, especially to children, and so far as anyone can really tell, it is of no value in any known disease.

All physicians can remember how, twenty years or so ago, benzyl benzoate flashed on the horizon, and soon was curing almost everything, including hypertension and leukemia. Today, about its only value seems to be in relieving some patients with painful menstruation.

One of the most curious features of the development of therapeutic practice is the way in which the medical profession will give up a drug, which, according to most reports, is still curing in 90 per cent or so of cases, to try a new one. One would think that men who had once found a marvelously efficient drug would never give it up. But to judge from articles in the journals in the last few years, the profession shifted its favor rapidly from gastric mucin to vegetable mucin, then to a mixture of foreign protein and emetine, and then to commercial brands of histidine, all at a time when, to judge by the literature, each one of these substances was giving almost perfect results in the treatment of ulcer.

Today, sulfanilamide is being tried out in the treatment of all infections, just as salvarsan was tried out twenty years ago. Today, salvarsan is used in the treatment of syphilis, yaws, — some intestinal parasites, and little else. Similarly, in a few years the use of sulfanilamide will doubtless be restricted to a few types of infection.

Obviously, no one can object to the widespread trial of useful or supposedly useful drugs. The only objectionable feature of the process is the cluttering up of the literature with the first highly favorable reports of men whose enthusiasm must have outrun their judgment. Certainly when the excitement died down no one could duplicate their results. As some cynic once said to a sick physician, "For goodness sake, take a few doses of this new drug while it is still curing!"

Actually, what is one to think about the small mountain of enthusiastically favorable articles which is always piled up after the discovery of some new drug which takes the fancy of the profession. When, with the passage of time, it becomes obvious that the

writers were wrong—when tuberculosis no longer responds to the curative action of creosote, and high blood pressure no longer returns to normal under the influence of benzyl benzoate—what is one to think about the writers of the favorable articles? Surely they did not all consciously belong to the Ananias Club of Roosevelt the First. No, probably what happened in most cases was that these men never thought to carry out their therapeutic experiment in such a way and with so perfect a control group that a trained statistician could tell what value to place on the results. What with the natural tendency for many diseases to grow better, the commonly overpowering tendency of optimistic persons, physicians and patients alike, to fool themselves, and the lack of such wide experience as would tell a physician whether or not the results obtained with a new treatment are better than those obtained with old methods or none at all, it is little wonder that most of the reports as to the efficacy of new drugs are of no value. Worse yet, a new drug for the treatment of, let us say, ulcer, is usually given *in addition* to the usual dietary and alkalinizing treatment of ulcer.

Often then, as an editor looks at the pile of therapeutic reports that come to his desk, his tendency is to send them back; he hates to think of padding the files of his journal with a mass of articles which are almost certain to be worse than useless later. But then he will wonder, "Perhaps there is a grain of truth here, and I should not be denying it publication." But, as he rereads the long article with all its ease reports, he asks, "Is all this necessary? Why couldn't the man have said simply that he tried so-and-so's new medicine in thirty cases of ulcer, and his impression was that the patients did better than they would have done on diet and Sippy powders alone?" What reams of paper this would save, and actually how often the writer's object would be better served with the short, pithy, readable report than with the long tiresome one.

Other physicians, noting such a report, might be induced to make similar studies; they also might make short reports, favorable or unfavorable, and soon the rank and file of the medical profession would gain a good idea of what drugs are worth trying and what are not. Unfortunately, today, few men write unfavorable reports, perhaps because they assume that every paper must be a long and detailed one, and they haven't time to spend over a "dead horse." Actually, how helpful and simple it would be if soon after a new and popular drug was introduced, notes like this would appear: "I tried the drug in such and such dosage in twenty cases of this and that with apparently good beginning results in some. In two cases the results seem to be fairly permanent. In several cases I had to stop administration because of abdominal pain, diarrhea, and skin eruptions, and in one case the patient promptly died with a severe leukopenia. I have decided to stop using it. Signed"

Walter C. Alvarez, Rochester, Minn.

Book Reviews

The Principles and Practice of Rectal Surgery. By Wm. B. Gabriel, M.S., F.R.C.S., Surgeon to St. Mark's Hospital and Royal Northern Hospital, London. Second edition, 353 pages, illustrated. H. K. Lewis & Co., London, 1937.

THIS second edition of "The Principles and Practice of Rectal Surgery," by Mr. Gabriel, is presented five years after the publication of his first edition. This volume is a detailed record of the experience and progress in the diagnosis of rectal ailments and the practice of this branch of surgery, which the author has collected during his affiliation as surgeon to St. Mark's Hospital for Diseases of the Rectum since 1920.

It has been a pleasure for the reviewer to read a book so clearly written and well illustrated. The whole field of rectal surgery is covered in a most thorough and painstaking manner. Its contents are a record of the personal experiences of the author both from his hospital and his private practice. One reads a story of the progress and refinement in treatment of diseases of the terminal bowel.

The second edition is noted particularly for its newer work on surgical anatomy contributed in collaboration with Mr. O. V. Lloyd-Davies, M.S., F.R.C.S. and represents much of the recent work of Milligan and Morgan. Local anaesthesia has found its rightful place in non-suppurative lesions. The injection treatment for haemorrhoids has been found to be applicable in only about 40% of the cases. The operation of rectosigmoidectomy for intractable prolapse of the rectum is carefully described. Mr. Gabriel has made the timely observation that a certain percentage of fistulae-in-ano eventually become malignant. In the new material one also notes: the role of epidermophytosis in pruritus ani—injuries of the rectum—lymphogranuloma inguinale and many new refinements of technique and post-operative care.

The chapters on benign and malignant tumors of the terminal bowel are thorough and extremely well written. Mr. Gabriel's perineo-abdominal operation for cancer of the rectum presents itself as one of the most important features of the volume. The role that benign adenomata play in rectal cancer has been emphasized. This book can be highly recommended to those who seek a special knowledge of diseases and injuries of the terminal bowel.

E. A. Daniels, Montreal, Canada.

Practical Methods in Biochemistry. By Frederick C. Koch, Ph.D., Professor of Biochemistry, University of Chicago. Price, \$2.25. 302 pages, 17 figures, Second Edition. William Wood & Company, Baltimore, 1937.

THIS excellent laboratory manual of Biochemistry for medical students has been carefully revised and brought up-to-date. The book is excellent in regard to the choice of experimental methods, the clarity with which the methods are described, and the choice and presentation of tabular material.

The general laboratory instructions, included as an

appendix, are exceptionally worth while and every student technician, laboratory worker, or physician, who occasionally does work in the chemical laboratory, would do well to read this part of the book even if he or she did not read the remainder. The first sentence of this appendix reads: "Orderliness, intelligent manipulation, neatness and precision are absolutely necessary for success in any laboratory work."

A. C. Ivy, Chicago, Ill.

Traitement des Constipations Fonctionnelles Treatment of the Functional Types of Constipation. By Gabriel Leven et Roland Leven Masson et Cie Paris, 1938.

A BOOKLET of some 87 pages in which the authors make pertinent remarks, on what may be regarded by a few as a commonplace subject but nevertheless presents in a concise manner the authors' viewpoints on constipation and auto-intoxication, based on clinical observations and laboratory findings.

One is to bear in mind of what vital importance is the defensive barrier played by the intact intestinal mucosa in constipation and the therapeutics thereof is to maintain a sound intestinal mucosa.

Furthermore, the frequency of the spastic type of constipation even in elderly patients indicates that the treatment must take into account the relief of the spasm.

Whilst we are fully aware how a treatment based on drastic purgatives the misuse of enemas and the abuse of a roughage diet, in the presence of such findings is foolhardy; we fail to grasp why such a treatment must be considered as the classical technic in contrast to the treatment advised by the authors which as they maintain, respects the intestinal mucosa and relieves the spasm.

There is some interest in recognizing three distinct functional types of constipation: (a) constipation appearing as a spurious symptom met with so often in infants as well as adults, being the outcome of defective hygiene, malnutrition or obesity; (b) physiological constipation, which makes its appearance following an operation, or pyrexia, and most frequently met with in vicarious vomiting of pregnancy. This constipation should not be tampered with; being a physiological phenomenon of defense; we should mark time and wait for the spontaneous return of stools in all these cases. There are numerous cases to illustrate this point. We doubt, nevertheless, if most surgeons will subscribe to this mode of thinking: (c) pathological constipation, medical or surgical. Under this heading the authors consider only that type of constipation which is the outcome of a medical condition such as hyperchlorhydria, in which, increased acidity brings about spasm of the intestinal tract; biliary tract infection, aerophagia and dystrophy of the abdominal muscles.

More debatable is the author's viewpoint, that some intestinal anomalies such as dolichocolon may be responsive to medical treatment.

Following this exposé the second part of the work is given to a brief outline of the therapeutic methods employed in relieving the spasm present in the intestinal tract and in protecting the intestinal mucosa against further damages.

The full armamentarium, from the avoidance of roughage food to glandular therapy; the treatment of anal fissures, and hemorrhoids; gymnastics and massage, must be taken into account whilst dealing with this topic on therapeutics. The authors speak highly of the good results obtained by sodium bromide in spastic constipation and the most encouraging effects of sodium cacodylate used as a suppository in anal fissures.

In addendum, the authors have demonstrated by sketches their method in applying the abdominal band in constipation with enteroptosis, a most ingenious and interesting procedure.

A. Cantero, Montreal, Canada.

Cirurgia de Megaesôfago. By Edmundo Vasconcelos and Gabriel Botelho. Sao Paulo, Companhia Editora Nacional, 434 pp., 1937.

VASCONCELOS and Botelho, working with a number of associates, have prepared an interesting volume of 434 pages on the problem of megaesophagus. This disease appears to be much more common in Brazil than in North America. The writers incline to the view that the trouble is due commonly to destruction of ganglions and nerves, not only in the wall of the esophagus but also outside in the vagal trunks. They believe also that these nerve changes are associated with a lack of vitamin B₁ in the diet, and a tendency to the development of beriberi. The writers describe in detail the various operations and procedures that can be used to overcome the cardiospasm. They describe also the innervation of the normal esophagus.

Unfortunately, the book is written in Portuguese, a language which is not well understood in this country, but it can be read fairly well by anyone who understands Spanish.

The Therapeutic Problem in Bowel Obstructions. By Owen H. Wangenstein. Published by Charles C. Thomas, Springfield, Ill., 1937.

IN a review of a large amount of experimental work on the factor of distension the author traces the pathogenesis of intestinal obstruction through its various stages and concludes that no direct and unequivocal statement of the lethal factors in intestinal obstruction has been made. The loss of fluids, leading to loss of electrolytes, elevation of non-protein blood

introgen and the shift to acidosis, occurs concomitantly with the changes in circulation, bacterial relations, and absorption from the bowel.

The recognition of obstruction is fully discussed as is the differentiation of large and small bowel obstructions. The check-valve action of the ileo-cecal valve is pointed out. X-ray films are valuable aids in locating the probable point of obstruction.

In the treatment of obstructions, saline solutions, blood transfusions, conservative decompression, and operations are indicated. Saline solutions and blood transfusions are indicated as pre-operative measures. In those cases in which incomplete obstruction is due to adhesive processes, and in which no strangulating mechanism obtains decompression by suction applied to a duodenal tube is best adapted. Likewise, partial obstructions associated with inflammatory lesions are frequent indications for this type of treatment.

Conservative suction decompression is contra indicated in any case in which strangulation of the bowel has occurred and those cases of acute obstruction of the left half of the colon, in which the colon has been converted into a closed loop by the ileo-cecal valve.

The "ear-marks" of successful decompression are (1) cessation of gas pains, (2) decrease of distension, (3) visualization of gas in the colon, (4) less fluid aspirated through the duodenal tube, and (5) toleration of temporary discontinuance of the suction without recurrence of pain. No narcotics should be given to the patients receiving this treatment. In support of the view that there is probably no toxic absorption factor in small bowel obstructions the author points out that no evidence of such absorption is seen as long as the bowel wall remains viable.

The most important single factor in the operative treatment of these cases is the rigid observance of strict asepsis. When a closed loop of colon is found it may be wise to establish an ileostomy passing the tube down through the ileo-cecal valve rather than attempt any manipulation of the cecum itself.

Part II deals with the diagnosis of acute abdominal disorders and describes the indiscriminate employment of laparotomy as a diagnostic procedure. The possible methods of treatment are discussed in detail and the management of the suction apparatus shown. Excision of non-viable bowel with the establishment of a double barrel enterostomy is recommended rather than immediate anastomosis. Post-operative treatment is discussed in detail.

In Part III all of the unusual and rare causes of obstruction and their distinctive features are discussed.

Large bibliographies and numerous figures accompany each part of the book.

York.

In Infant Feeding

HORLICK'S MALTED MILK has been used suc-
cessfully for over a half of a century. It has been found
especially useful because of its ease in digestion. Many
an undernourished baby has been able to respond to
the nourishment, the safety, and the uniformity of this
low curd-tension milk-food.

In Horlick's, the enzyme and vacuum processing
not only modifies the ingredients, but also renders the
milk curd more fine and flocculent. Horlick's has been
found to be digested by infants with very delicate
digestive systems.

Horlick's offers a most flexible method of pro-
viding milk in a modified form for the bottle fed—first,
merely mixed with boiled water, and later on by the
gradual introduction of additional milk, when indicated.

We invite your trial—

Samples gladly sent upon request.

Please enclose your letterhead or card.

» » EXERCISE « «

Exercise is an important factor in the treatment of constipation. Of equal importance are suitable diet and a regular habit time for bowel movement, which under the present mode of living, are often difficult to enforce. For the patient who is unable to exercise or adhere to a suitable diet a regular bowel

movement may be brought about and maintained with Pétrolagar. It assists in establishing a regular bowel movement because it mixes intimately with the feces to form a soft, easily passed stool. Pétrolagar is prepared in five types for choice of medication. Pétrolagar Laboratories, Inc. • Chicago, Ill.

Pétrolagar — Liquid petrolatum 65 cc. emulsified with 0.4 Gm. agar in a menstruum to make 100 cc.

Pétrolagar

THE ASSOCIATION FOR THE DEVELOPMENT OF MEDICAL RELATIONS BETWEEN FRANCE AND FRIENDLY NATIONS

The President of the A.D.R.M., Professor Henri Hartmann, Paris, has organized for June and July, 1938, post-graduate courses in English, which will be presented at the Faculty of Medicine, as well as in the hospitals of Paris, under the direction of the professors, physicians, surgeons and specialists of the hospitals.

June 27 to July 2: *Hospitol de la Pitié*: a week in **CARDIOLOGY**, under the direction of Professor Clerc, from 10 to 12 a. m., case presentations, radio-scopic, electrocardiography, etc.

June 27 to July 2: *Hôtel-Dieu*: a week in **OPHTHALMOLOGY**, under the direction of Professor Terrien: ophthalmological technique, clinical and laboratory examinations, each morning from 10 till noon.

June 27 to July 2: *Hospital Broca*:

DUOCHOL (PLESSNER)

to promote BILIARY DRAINAGE

SPECIFIC MEDICATION in specific biliary conditions

Plessner bile salt preparations present specific medication for specific lesions of the hepatobiliary tract.

TAUROCOL (Plessner)

Taurocol is of unusual therapeutic value in mild chronic cholecystitis. Containing bile salts, stomachics, and laxatives, it enhances biliary drainage and stimulates intestinal peristalsis.

TAUROCOL COMP. (Plessner)

Contains pepsin and pancreatin in addition to the ingredients of Taurocol. Indicated when gastric or intestinal indigestion complicates gallbladder disease.

Duochole (Plessner) fulfills every demand of the modern therapeutic approach in chronic cholecystitis, toxic hepatitis, stone-free cholangitis, and as an aid in the prevention of gallstones in cholecystitic involvement. Its combination of highly purified bile salts with sodium salicylate increases the flow of bile from the liver, and improves gallbladder emptying, in this manner promoting biliary tree drainage with its beneficial therapeutic influence.

The reasonable price of Duochole (Plessner) makes it particularly advantageous in the many cases where prolonged administration or frequent repeated courses of therapy are required.

Generous samples of all Plessner bile products, together with literature, sent on request.

THE PAUL PLESSNER CO., DETROIT, MICH.

Why Beta Lactose?

1. Tests Prove that Borden's Beta Lactose is 5 times more soluble than ordinary milk sugar (alpha lactose). So, it's *easier* to use.

3. *Easier to Use* and easier to take, Borden's Beta Lactose is particularly helpful in conjunction with *B. Acidophilus* therapy, where as much as 2 ounces of milk sugar must be ingested daily. Send coupon below for full information and trial supply.

2. Trying It Proves That -- in water or in food -- Borden's Beta Lactose is much more palatable than ordinary milk sugar. So, it's *easier* to take.

a week in GYNECOLOGY, under the direction of Professor Mocquot, clinical examinations, operations, insufflation of the tubes, etc., each morning from 10 till noon.

June 27 to July 2: A week devoted to ENDOCRINOLOGY, by Professor Charles Richet, in the afternoons.

July 4 to 9: A week in PEDIATRICS in the various children's hospitals, by Professors Lereboullet and Debre and Dr. Armand-Delille. Clinical examinations in the mornings and ward rounds and infant feeding in the afternoons.

July 4 to 9: One week in NEURO-

PSYCHIATRY in the various hospitals with the collaboration of Professors Guillaïn, Clovis Vincent, Alajouanine, Hagueneau and Dr. Worms.

July 4 to 9: Hôpital Saint-Louis: A week in DERMATOLOGY, both mornings and afternoons, directed by Professor Gougerot.

July 4 to 9: Cancer Institute at Villejuif: Each morning from 9 till 11, Professor Verne will demonstrate normal histological technique and tissue culture.

July 4 to 9: Faculty of Medicine: Physiological Laboratory: Professor Binet and Dr. Bargeton: Medico-

surgical Physiology: Theory from 2 to 3 p. m.; practical demonstrations from 3 to 5 p. m.

July 4 and 5: Hôpital Cochin, mornings and afternoons Professor Chevassu will demonstrate urological diagnosis including pyelography.

July 6 to 12: Hospice de la Salpêtrière, each morning from 10 to 12, Professor Gosset will direct instruction on Abdominal Surgery (stomach, intestines and biliary apparatus). In the afternoons Dr. Thalheimer will review operations using the cadaver as subject.

The fee for the courses of study is 300 francs for 6 mornings or 6 afternoons and 500 francs for mornings and afternoons. For registration and reservations address the Bureau d'I. A.D.R. M., Salle Beclard, Faculté de Médecine, Paris, VIe, France.

Zymenol

Yeast Enzymes in Oil Emulsion

In

CONSTIPATION or COLITIS

Restores daily, bulky bowel movement with no irritation, gripe or strain — without irritative, stimulant drugs, roughage or artificial bulk.

Evacuation is the result of the catalytic activity of the enzymes, Invertase and Zymase plus potent Vitamins B-G, proven to restore intestinal muscular tone.

ZYMENOL is safe for infants or the aged. Sugar free, ideal for diabetics. Small teaspoon dosage, no leakage — less expensive.

For the Aristocracy of Thought

Your highly valued Journal is made to order for the aristocracy of thought of the Medical Profession of America . . . it has become a habit with me, and I would not care to miss a single issue.

The AMERICAN JOURNAL OF DIGESTIVE DISEASES

Was NOT established as a *vade mecum*, a news magazine, a humorous monthly nor a fictional alleviation for the jaded nerves of busy doctors . . . Most readers by this time have divined this point of policy, and have come to know that, month by month, this periodical gives a cross section of current and modern gastro-

enterological thought. It sees most of the manuscripts in this specialty: it prints all of them that are suitable . . . BETTER articles will be printed only when BETTER articles are written. The reader may confidently believe that at present the best work in gastro-enterology finds its way into these pages . . . Another way of saying that the management of this JOURNAL is seeking to perfect a really worth-while Archive in a most important field.

It is the firm intention of the Editorial Council that the pages of this Journal shall be kept FULL of important matter, and entirely EMPTY of all matter that is irrelevant . . .

Readers feel today that an important contribution to American Medicine is being, and will be, made through the agency of the American Journal of Digestive Diseases . . .

I am an admirer and reader of your excellent magazine.

You cannot improve on the editorial content—it is and should be, an outlet for scientific thought.

Material and format are excellent. I enjoy it very much because the articles are scientific.

It is certainly a well edited Journal and anyone who subscribes to it certainly gets his money's worth.

Quality brevity, educational value, scientific dignity, good typography and singleness of purpose are making friends in increasingly large numbers.

No Other Special Medical Journal Ever Made the Subscription Showing in 4 Years That Has Been Accorded to the American Journal of Digestive Diseases

With only the numerically small American Gastro-enterological Association as a formal backer, this Journal has independently attracted a record group of constant readers.

WHY?

The reasons are obvious—

- One of the strongest Editorial groups in American Medical Journalism, realizing the void that existed in gastro-enterological literature, determined to make a special Journal that would meet very specific needs.
- The needs were for a journal that would collect and attract under one head the important contributions in this field, thus enabling the reader to learn what he wished without the inconvenience of looking through an extensive literature.

• This has been done . . . today our Editor receives countless manuscripts from the investigators of the U.S.A. . . . today numerous readers volunteer the fact that they have never made better investments than in the Volumes of the American Journal of Digestive Diseases.

Spend \$6.00 per year or \$10.00 for two years NOW.

Join the increasing Group of doctors, whose enthusiasm has made and is making history in American Medical Journalism.

Mechanism of Shock: Effects of Intravenous Injection of Salt Solution in Collapse Induced by Mechanical Impounding of Blood in the Splanchnic Region in Normal and in Hyperthyroid Dogs. Arch. Path., 25:2-149, Feb., 1938.

The authors start with the fundamental principle that the pathologic process in shock is the impounding of a large volume of stagnant or slowly flowing blood in dilated capillaries in some specific region or more diffusely throughout the body. This process results in the reduction in the volume of the circulating blood, the loss of fluid from the blood, an increase in its concentration, and an anoxemia of the tissues and organs in which the blood is impounded. Because of this shunting of a portion of the circulating blood into the dilated vessels the heart does not receive enough blood to maintain a normal systemic pressure. As attempts to increase the volume of the circulating blood by intravenous injection of fluids is usually of temporary value and as the mechanism of these processes is little understood, the authors studied the problem from experiments in which warm physiologic salt solution was injected intravenously into dogs in which a part of the blood volume had been impounded by mechanically constricting the hepatic veins after the method of Simonds and Brandes. These experiments afforded them the following observations.

When blood is impounded in the liver and gastro-intestinal tract by constricting the hepatic veins the systemic blood pressure falls immediately by 25 to 70 per cent and remains thus for at least thirty minutes.

Injection of physiologic salt solution during the period of constriction of the veins in quantities up to or more than the estimated original blood volume causes a rise in pressure during the period of injection, but it falls again within one to three minutes after the injection is stopped.

The blood volume after injection and while the constriction is on is usually a little greater than the original estimated initial volume plus the salt solution injected. Blood volumes similarly computed after release of the constriction were always much lower.

The rate in fall of blood pressure and reduction in blood volume after injection of salt solution under the conditions of these experiments indicate the rapidity with which fluid escapes from the circulating blood when a considerable part of its total volume is impounded in a known region of the body.

A surprising amount of fluid was found to have escaped into the lumen of the stomach and into the gastric

Bromo-Seltzer

Its Place in GASTRO-ENTEROLOGY

There is a world of difference between the gentle *systemic* action of the sodium citrate in BROMO-SELTZER and the harsh *local* antacids such as the bicarbonates. While the latter often damages the normal hydrochloric acid of the stomach, sodium citrate actually aids digestive processes. This has been established by its use in infant feeding, with milk coagulation prevented and a fine flocculation produced.

Gastric Sedative and Analgesic—The sedative and analgesic value of BROMO-SELTZER are widely recognized by the profession. In gastro-enterology, it exerts a gentle sedative action upon the stomach and offsets nausea. Nervousness is minimized.

BROMO-SELTZER is dependable without harmful after-effects or mental depression. Its bubbling effervescence makes it decidedly palatable.

Try BROMO-SELTZER in your practice. Generous samples and literature upon request.

MARYLAND

submucosa. The peritoneal cavity contained relatively little fluid, the retroperitoneal tissues and the walls of the gall bladder and small intestine were moderately edematous.

Thyrotoxicosis caused a variation in the blood pressures from those noted in the normal dogs. The pressures were lower to begin with, fell to a lower point after completion of the injection, and did not rise as high after release of the constriction on the hepatic veins.

N. W. Jones, Portland.

BOYD; JULIAN D.

Changing Concepts of Normal Nutrition. Northwest Medicine, 37:71-75, March, 1938.

It is the author's opinion that suboptimal states of nutrition are widespread in this country, due to the types of food customarily eaten. He discusses more specifically vitamin D and mineral requirements as related to bone mineralization and tooth decay, and normal vitamin A requirements. This is especially important during childhood, since many characteristics of the

adult body are determined on the basis of adequacy of nutrition during the period of growth. Such nutritional deficiencies do not become obvious until the status of groups receiving prevalent diets is compared with that of those under a wisely supervised nutritional regimen. Then it becomes apparent that states of inferior physique, minor disturbances of health and some types of disease are most frequently dependent primarily on suboptimal diets, and may be prevented or corrected through qualitative and quantitative control of the constituents of the diet. Hanes M. Fowler, Fort Wayne.

Vegetables Bred-Up For High Mineral and Vitamin Quotas in Appetizing Strained Food Form

Offsets tendency to anemia commonly caused by restricted diet in gastro-intestinal conditions, also useful in low-bulk and other special dietaries.

Vitamin and mineral content and other nutritive elements in Gerber's vegetables have been built up by ten years of continuous scientific effort. Seed strains have been bred for higher nutritive content and improved flavor. Soil is selected for the needs of each vegetable, analyzed and improved by the proper type of fertilizer.

Fields are less than an hour from kitchens, to avoid loss of food value from longer transportation or storage. Crops are harvested at almost the hour of their perfection. Cooking processes have been designed to conserve minerals and vitamins, often lacking in restricted diets.

Gerber vegetables and cereal are salt-poor, sugar-free, and low in fiber. Qualitative and quantitative analyses of each food are available to physicians on request, to enable them to be sure of precise nutritive values.

CONNOTATIONS

By H. J. SIMS, M.D., Denver, Colorado

Fabrieus in 1592, published his first surgical work. It was named: "The Pentateuch (five books) Of Surgery."

Leriche called attention to the sympathetic nerve plexuses which are said to lie in the intimate sheath of the large arteries and specified that certain definite results follow excision of these structures. The removal of the structures was designated by him "sympathectomy" and was actually accomplished by his teacher, Jaboulay in 1883.

Hartley of New York, was long attributed as having removed the gasserian ganglion. Foote of Cincinnati, in 1869, carried out the same procedure.

Dr. Joseph Guillotin in 1789, proposed that execution should be free from torture. He devised a machine known as the guillotine. Oddly, this name is given to a number of modern surgical instruments because of the principle of their mechanism.

Osteochondritis of the vertebral body was first described by Calve in 1924.

Glossitis Rhombica, a benign disease of the tongue, was described by Brocq and Pautrier in 1914.

Guthrie in 1934, devised a urethrotomy for incision of the bladder neck. In 1874, Bottini proposed that the obstruction should be incised by the cautery and devised such an instrument.

The Royal College of Surgeons of England have on exhibition a mummified liver with gall bladder calculi. It is a specimen of a priestess of Amenon of the XXI Dynasty (about 1500 B.C.).

Griffin in 1912, reviewed 650 cases of diaphragmatic hernia, only fifteen were recognized before death. In a series of sixty operated cases, recorded by Harrington, the preoperative diagnosis was confused with cholecystitis in 29 cases; gastric disease in 23 cases; and in 7 instances, heart disease.

Seabolew in 1902, first suggested that the pancreas of new-born calves would prove to be the source of internal secretion. Schafer in 1916, proposed the name of insulin.

Laenneck in 1806, described the forms of melanomata in man. Moore in

Useful... IN MANY INVALID AND CONVALESCENT DIETS

*R*IPPE BANANAS are a natural, soft, bland food . . . with a delicate flavor . . . popular with most persons . . . nourishing . . . easily digested . . . mildly laxative . . . non-irritating . . . do not readily ferment in the intestines . . . create intestinal conditions unfavorable to the growth of putrefactive bacteria . . . yield alkaline mineral residues in the body.

Because of these attributes, together with their soft fibre, pectins, high content of sugars, satiety value, low content of protein and fat, their vitamins (good source of A-B-C-G) and essential minerals, ripe bananas are prescribed by an increasing number of physicians in many invalid diets, including: ulcerative colitis; peptic ulcer; cardiac; diabetes; liver disorders; nephritis; tuberculosis; as well as in various post-operative and convalescent diets.

In the field of corrective diets, physicians are finding that ripe bananas help combat both diarrhea and spastic constipation; also that in combination with milk they constitute a basis for planning a variety of effective, safe reducing diets for persons who are overweight.

LITERATURE ON REQUEST.. ADDRESS

UNITED FRUIT COMPANY *Educational Dept., Boston, Massachusetts*

1857, described melanoma of the rectum. Such tumors have long been known to occur in animals.

Reclus in 1883, recognized cystic disease of the breast which he termed: "maladie kystique de la mamelle."

Gibson and Malet in 1879, described a case of cleft sternum.

Zenker in 1862, described a case of fat embolism occurring in man.

Seabangew in 1895, attempted to remove an embolus from the femoral artery.

Ardakoff in 1876, was the first to report that the blood of a burned animal was toxic to healthy animals.

Langerhans discovered the islands in the pancreas which bear his name in

1867. Laguesse in 1893, first suspected they produced an internal secretion.

Mering and Minkowski in 1889, removed the pancreas of a dog and taught the cause of diabetes.

Pertussis disease was first described by Legg of Baltimore, in 1909.

Monro in 1797, described a case of myomata of the esophagus.

Jellinek in 1929, described two instances in which bone trauma resulted from electric shock. Burrows of London has recently described a fracture of the head of the humerus, following a shock from 50 cycles alternating current of 230 volts.

Pare in 1610, and Fabricius Hildonus in 1646, each reported two cases of

traumatic diaphragmatic hernia. The first congenital case was reported by Lazars in 1689. Guthrie in 1888, proposed laparotomy for reducing a diaphragmatic hernia.

CONNOTATIONS

By

H. J. SIMS, M.D.

DENVER, COLORADO

Traumatic intrathoracic rupture of the thoracic duct was reported by Bartolet in 1663. Quinke, in 1875, gave an authentic description.

The first omentopexy for portal obstruction with ascites was performed by Van Meulen in 1899 at the suggestion of Talma. The patient died of shock. Morrison, in the same year unknowingly repeated the same procedure with results.

Gould, in 1855, performed one of the earliest jejunostomies for feeding purposes on a patient suffering from carcinoma of the pylorus. The operation was performed under a carbolic spray. The wound was dressed with salicylic wool.

Willett, in 1876; Heath, in 1879; Bull, in 1885, and McGill, in 1866, unsuccessfully attempted to suture a ruptured bladder. McCormack, in 1869, published a report of two successful instances.

In 1833, Myer gave a description of the carotid body and pointed out its common situation at the bifurcation of the carotid artery.

Intracranial calcification is rarely encountered. Heuer and Dandy found only seven cases reported up to 1916, and these by foreign observers.

Complete excision of the scapula was attempted by Lagenbeck in 1855.

Cardamus, in 1556, advocated that people hopelessly immoral should be transfused with blood of those strongly immoral. Evidently, blood transfusion was practiced at this time.

Dr. Werdt of Hamburg, in 1552, disguised himself as a woman to witness the birth of a child. He was recognized and burned alive. Childbirth at this time was in the hands of women of low caste. The aid of priests or men possessed of mystic powers was sought only in difficult cases.

Sir Astley Cooper, in 1829, recognized tuberculosis of the breast. He described the microscopic features as a "scrofulous swelling of the bosom." Dunbar, in 1881, recognized the microscopic features of the disease.

Lieutaud, in 1779, is thought to have recognized a disease now known as linitis plastica. Andral, 1829, attempted to describe the lesion, and to him is credited the report of the first case. Since recognition of the condition, more than forty names have been used to designate its description.

Orthmann, in 1888, first described

SEASONAL PRESCRIPTION FORMULAE

Improved in Palatability. Tolerance. Clinical Efficiency. By Effervescence—Alkali Buffers.

• Salici-Vess

—Combines two standard, safe forms of anti-rheumatic medication, sodium salicylate and sodium iodide, with alkali buffers in the more convenient, more acceptable form of an effervescent tablet.

Gives quick symptomatic relief—easy to take, well tolerated. Tubes of 30.

• Aspir-Vess

—Combines the analgesic, antipyretic effects of acetyl salicylate (sodium salt of aspirin), protected by alkali buffers, in the convenient form of a palatable, effervescent solution. Tubes of 25.

	120 cals.
1 oz. wt	28 grams
	90 cals.
1 teaspoon	15 cals.
1 tablespoon	60 cals.

Feeding newborns is relatively simple, consisting chiefly of milk and carbohydrate. Their digestive organs are well adapted to care for breast milk, but for lesser amount of cow's milk. Hence the need for modifying cow's milk to the newborn's digestive capacity.

Whatever milk is indicated, Karo makes the effective modifier. Karo Syrup contains a large proportion of dextrin with relatively small amounts of maltose, dextrose and sucrose. The Karo formula may be readily adapted to most newborns.

Infant feeding practice is primarily the concern of the physician, therefore, Karo for infant feeding is advertised to the Medical Profession exclusively.

For bland diet therapy, especially ULCER cases ... PABLUM

FAR too often the bland diet prescribed for gastric ulcer, colitis, and similar gastrointestinal disorders is a deficient diet. Pablum is the only food rich in a wide variety of the accessory food factors that can be fed over long periods of time without danger of gastrointestinal irritation. Its fiber content is only 0.9%. Yet Pablum contains 37 times more iron than does farina and is an excellent source of vitamins B₁ and G. Also rich in calcium and phosphorus.

Requires no cooking. Pablum can be prepared quickly and conveniently at the office or shop simply by adding milk or cream and salt and sugar to taste. Can also be used in a variety of appetizing dishes to enhance their vitamin and mineral values. Pablum (Mead's Cereal thoroughly cooked) consists of wheatmeal (farina), oatmeal, cornmeal, wheat embryo, alfalfa, yeast, beef bone, reduced iron and sodium chloride.

primary carcinoma of the fallopian tubes.

Volkman, in 1822, described contracture of the muscles of the leg in a sixteen year old boy, following application of a splint and a compression bandage. He believed arterial obstruction the principal causative factor. Murphy, in 1914, from experimental work, concluded such a condition was a result of venous obstruction. He stated, "The lesion in Volkmann's contracture is a surgeon's lesion and never a lesion due to trauma." Two years later, he reported a typical instance of Volkmann's contracture, in which no bandages or constrictors were used.

BROOKE, BANNER R.

Colonic and Rectal Cancer. Northwest Medicine, 37:81-83, March, 1938.

The author cites figures to substantiate his conclusion that the incidence of colonic and rectal cancer has increased during the past 15 years or so. He also stresses the importance of early recognition of the condition.

The incidence of rectal and colonic cancers is about equal, with about half as many located in the right side as in the left side of the colon. Gastric disorder, early tumefaction, and early cachexia are prominent symptoms of right-sided malignancy. Obstruction, partial or complete, and hordorgismus are found more often in left-sided cancer, but seldom in rectal cancer. Bright blood in the stool must always be regarded as possible cancer. Sigmoidoscopy and colon roentgenogram should be demanded at once. These procedures should be repeated, if the bleeding persists, until its site has been determined.

The public must be informed of these early symptoms even at the risk of increasing cancerphobia and neurosis. The profession must be more alert in the early identification of colonic and rectal cancer.

Hanes M. Fowler, Fort Wayne.

MANVILLE, IRA A.

Topical Applications of Cod Liver Oil in Treatment of Ulcerative Colitis. Northwest Medicine, 37:75-77, March, 1938.

The author reports a method of applying cod liver oil directly to the mucosa of the sigmoid and rectum by means of a spray nozzle inserted through a sigmoidoscope. He states that the few cases he has so treated for ulcerative colitis have been distinctly benefitted and he cites another report of beneficial results by the same type of treatment. A diagram accompanies the report explaining the construction and use of the apparatus.

3:PYRIDINE CARBOXYLIC ACID

(Nicotinic Acid)

TABLETS

Now Available to the Medical Profession

SMAcO

Physicians may now obtain SMAcO 3-Pyridine Carboxylic Acid (Nicotinic Acid) for clinical experimentation in tablet form for oral administration.

SMAcO 3-Pyridine Carboxylic Acid (Nicotinic Acid) Tablets, of both potencies are scored permitting a wide flexibility in dosage. Tablets may be broken in two parts at the score, enabling the physician to administer any multiple of 10 milligrams as a dose.

SMAcO 3-Pyridine Carboxylic Acid (Nicotinic Acid) is available in tablet form in the following packages:

Boxes of 10 One hundred-milligram tablets

Boxes of 50 Twenty-milligram tablets

Also available in crystals and ampoules

You may place your pharmacist order for any of the above packages in the regular way, or you may order Clinical Trial Packages as follows direct from us:

Boxes of 25 one-hundred-milligram tablets (SMAcO 7231) each

Boxes of 50 twenty-milligram tablets (SMAcO 7211) each

Boxes of 100 twenty-milligram tablets (SMAcO 7211) each

We do neither sell nor dispense drugs, we can only refer you to the nearest source for the direct purchase of the product.

CLEVELAND, OHIO

BASIC OPERATIONS IN COMMERCIAL CANNING PROCEDURES

III. EXHAUSTING OR PREHEATING

● Modern canning procedures provide for the exclusion from the sealed container of air, and other gases present in raw food material, to the greatest possible degree.

In the sealed can, oxygen, in particular, is undesirable, whether it be released from food cells or be present in the form of entrapped air. If present in the sealed tin container, oxygen can react with the food and the interior of the can and directly affect the quality, nutritive value and merchantable life of the canned food. Other gases—for example, carbon dioxide produced by cellular respiration—should also be excluded as far as is practical. If present in large amounts, these gases may place undue strain on the container during the heat process to which canned foods are subjected.

In commercial canning practice, certain operations—specifically the blanch—may aid in elimination of gases from raw food tissues. However, main dependence is placed upon what are known as “exhausting” or “preheating” operations, not only to expel gases from raw foods, but also to exclude air from the can.

Briefly, the exhausting operation is accomplished by mechanically passing the open can containing the raw food through a so-called “exhaust box” in which hot water or steam is used to expand the food by heat and drive out air and other gases contained in the food and in the can. The

times and temperatures used in commercial exhausting operations will naturally vary with the nature of the product (1).

After exhausting, the can is immediately permanently sealed, heat processed and cooled. During cooling, the contraction of the heated contents of the can creates the vacuum normally present in commercially canned foods.

With certain products, instead of exhausting as described above, the same effect is produced by preheating the food in kettles or similar devices; filling into the cans while still hot; and immediately sealing the containers. With still other products, an exhausting effect is produced by adding boiling water, syrup or brines to the food in the can. In some instances, exhausting is accomplished by mechanical rather than by thermal means. Specially designed sealing or “closing” machines are used to withdraw air and other gases by applying high vacuum to the can and immediately sealing on the cover.

Such in brief are the purposes of commercial exhausting operations and the means by which they are usually accomplished. Modern canners recognize that these operations are most important to the success of their canning procedures. They appreciate that only by strict supervision and control of exhausting operations can the quality and nutritive values of their products be maintained at a consistently high level.

VITAMIN B₁ FOR IMPROVED INTESTINAL TONE

Because recent studies have shown that vitamin B₁ has a beneficial effect on the tone of the intestines, this vitamin is receiving more and more attention as an aid in treating atonic constipation.

A good source of vitamin B₁ is Kellogg's All-Bran. Notice below how the vitamin B₁ content of All-Bran compares with that of other foods.

The presence of this vitamin, in such plentiful quantities, in a food which also contains natural "bulk," is being recognized as a further reason for recommending this laxative cereal.

A Natural Laxative Cereal

CONNOTATIONS. By H. J. Sims, Denver, Colo.

Many writers credit Petit with reporting the first case of eventration of the diaphragm. It is frequently stated in literature that Petit recorded his case in 1790. However, Petit died on April 20, 1750. The name eventration was given to the disease by Beclard who was mentioned in the writings of Cruveilhier. Marsh, in 1867, reported the first instance of its clinical recognition with autopsy findings.

Cruveilhier, in 1829, accurately described a cranial epidermoid, although Leprestre and Dupuytren had previously described similar neoplasms. In 1838, Johannes Muller contributed an excellent monograph on this subject.

Little first visualized the possibilities of colostomy after observing in an infant a congenital division of the rectum. Such a procedure was carried out by Pillare, in 1776.

Bernays was the first in America to successfully remove the entire stomach. In 1894, he performed the first cesarean section for placenta previa.

The use of zinc peroxide as an antiseptic dressing was suggested by Ellias, in 1903.

Hippocrates recognized and described ischiorectal abscesses. Celsus, 400 years later, advised the use of the knife in the treatment of fistula. One thousand years after Hippocrates' observation, Paul of Aigina, not only described fistulas and their complications, but offered principles in their surgical treatment which is now recognized.

Dugas sign (L. A. Dugas, 1806-1884) "If the fingers of the injured limb can be placed by the patient upon the sound shoulder while the elbow touches the thorax, there can be no dislocation, and if this cannot be done, there must be a dislocation."

Extradural nonparasitic cyst of the midthoracic region was recognized by Schlesinger, in 1898.

Sir Astley Cooper, in 1829, described tuberculous disease of the breast as a "serofulous swelling of the bosom." Virchow believes the breast immune to tuberculosis. Lancereaux, in 1860, was the first to establish the diagnosis by microscopic examination. Cuneo, in 1868, isolated the organism from the pus and successfully inoculated an animal with it.

In 1888, Anton and Fütterer isolated the *B. typhosus* from the gall bladders of fatal typhoid fever cases.

CONNOTATIONS. By H. J. Sims, Denver, Colo.

The rapid formation of renal calculi following injury to the spinal cord was first commented upon by Costello, in 1833. He stated Earle had previously described several cases of lithiasis attributable to injuries in the lumbar region. In 1835, Muller stated that in approximately 10 per cent of the cases of fracture of the vertebrae when accompanied by paralytic symptoms result in formation of kidney stones.

Aufrecht, in 1850, reported a case of primary myoma of the right saphenous vein originating in the region of the internal malleolus. Boettcher, in 1867, reported a similar case involving the ulnar vein.

Duodenal ulcer following external burns has often been reported in the literature, the first description being by Long, in 1810, and by Curling, in 1842.

A higher incidence of Osgood-Schlatter's disease has been reported among the Japanese. Kato suggested that the increased incidence is a result of frequent kneeling.

Hodges, in 1880, coined the term "piloid" sinus from the Latin *pilus*, meaning hair, and *nidus*, meaning nest. He believed the lesion to be due to invaginations of hairs in the postnatal fold. Warren, in 1867, probably recognized this anomaly and suggested that it be a result of change in growth of the hair follicles in the sacral region.

Aberrant pancreatic tissue was recognized by Klob, in 1859. Zenker, in 1861, attributed it to the formation of an additional pancreatic bud from the foregut which developed as an independent mass which had been carried away from its point of origin.

Lateral dislocation of the wrist is apparently rare. Ore

HEMATINIC PLASTULES

Recovery from hypochromic anemia, in cases treated with Hematinic Plastules, is usually rapid and unrestrained as evidenced by the early increase in the hemoglobin of the red blood cells. The suggested daily dose of only three Hematinic Plastules Plain replaces massive iron feedings and diminishes the likelihood of gastric disturbances, constipation and diarrhea Hematinic Plastules provide ferrous iron and vitamins B and G in soluble gelatin capsules, available in two types, Plain and with Liver Extract. Inquiries from physicians are given prompt attention.

BILE SALTS

Fairchild

The sodium glycocholate and taurocholate, the salts of conjugated colic acids in their native association as separated from fresh ox-gall.

A stable dry powder; uniform in composition; efficient for the well known therapeutic uses of ox-gall—in disorders due to faulty bile functioning.

Bile Salts preferably to be dispensed in capsule by itself, or in combinations in powder.

Offered in powder. ¼ oz., 1 oz. vials; in capsules, each three grains Bile Salts.

Fairchild Bros. & Foster

New York

of the first recorded cases was mentioned in the Bulletin de la Société de Chirurgie de Paris, in 1874. Another instance was noted in a manuscript on Fractures and Dislocations by Hamilton, published in 1884.

Cystic hygroma of the neck is a rare condition. Arnold, in 1865, concluded that a congenital defect represented the underlying cause.

Struma lymphomatosa, a rare type of abnormality of the thyroid gland was first described by Hashimoto, in 1912.

Piedel, in 1883, described a peculiar inflammatory condition of the thyroid gland which led to the formation of an iron-hard tumor. Twelve years later he observed a second case and in 1896, he published his observations of the disease to which he gave the name *eisenharte Strumitis*. Bowey noted a similar case, in 1885, and described it as a fibrating fibroma.

OPPENHEIMER, G. D.

Recurrent or Residual Progressive Ileitis. J. A. M. A., 110:1103, April 2, 1938.

The author reports the case of a 28 year old Jewish man who on January 18, 1928, was admitted to the hospital with the complaint of colicky abdominal pain unrelated to meals and of three weeks duration. On the day of admission the pains became more severe and localized in the right lower quadrant. Clinically the condition was considered an abscess of the appendix. Laparotomy was done, the appendix removed and the area drained. The convalescence was stormy, the temperature being 107.6° F. on the first post-operative day, but he was discharged on the twenty-first day.

Eight months later the scar broke down, drained a purulent material, and then healed spontaneously. On May 5, 1931, the patient was readmitted with the complaint of pain over the scar for the past two weeks. The temperature was 103° and there was a fluctuant mass beneath the scar. This was incised, pus evacuated and three days later fecal drainage was noted. Iodized oil was injected and revealed a fistula communicating with the cecum. The patient was then discharged with moderate fecal drainage. On July 31 he was readmitted but conservative measures were decided upon and he was again discharged.

On October 27 he was again admitted with the complaint of weight loss, febrile episodes, and abdominal pain for the past month. The fistula was still present and was studied with X-ray and iodized oil. Laparotomy was done, the ileum and 12 cm. of the ascending colon were resected and an isoperistaltic ileotransverse colonic anastomosis was done. Pathological examination of this revealed hyper-trophic chronic ulcerative inflammation of the colon.

Follow-up showed the patient to be well until June, 1936, when he developed watery stools and epigastric pain. Operation was again performed on November 7, 1936, and an ileosigmoidal side to side isoperistaltic anastomosis was done. To date the patient is carrying on as a normal individual.

From these results the author thinks it is not possible to differentiate between a residual and recurrent lesion and that when resection is done the ileum should be divided at least 8 to 12 inches proximal to palpable or visible involvement. In addition the operator should examine the ileum carefully far above the lesion so as not to skip an involved area.

LIDLAW, GEORGE F.

Nesidioblastoma, the Islet Tumor of the Pancreas. Amer. Jour. Path., XIV, 2:125, March, 1938.

The author gives a microscopic study of 9 "adenomas of the islets of Langerhans" removed surgically from 6 patients. Clinically it is of interest because these tumors

2 SIMPLE WAYS

of Preparing Palatable High Concentrations of KNOX GELATINE

PHYSICIANS are constantly asking us for formulae for the preparation of Knox Gelatine in a concentrated palatable form, useful in the dietary treatment of such conditions as muscle fatigability and gastric ulcer. Research on such formulae has shown these to be excellent.

"The Knox Fruit Stir"

Place the contents of 2 envelopes of Knox Gelatine in an ordinary saucer or cereal dish. Add 8 tablespoonfuls of any desired fresh or canned fruit juice, such as grape juice. Let soak for five minutes and eat with teaspoon.

*Total: 4 ounce mixture —
about 100 calories*

"The Knox Milk Stir"

Place the contents of 4 envelopes of Knox Gelatine in an ordinary drinking glass. Add 4 ounces of cold milk and allow to soak for five minutes. Add 2 more ounces of milk and stir until thoroughly soaked. Then place glass in small cooking kettle of hot water until gelatine milk mixture is thoroughly dissolved. Add 2 more ounces of cold milk, which will bring the temperature to a satisfactory warm drink of about body heat. A tablespoonful of prune juice or a few drops of any bland flavor like vanilla may be added.

Total: 8 ounce liquid — about 250 calories

They are ideal when frequent feedings and extra calories must meet adequately the level of nutritive requirement. Indicated to allay the pain in the gastric ulcer patient when given hourly. An adequate food adjunct both from the standpoint of easy digestibility or "low residue" in gastro-enteric dysfunction or intestinal stasis. Also of value for their high amino-acetic acid (glycine) content in dystrophic muscular conditions.

Why You Should Insist on Knox Sparkling Gelatine

Because Knox Gelatine is 85% protein in an easily digestible form — because it contains absolutely no sugar or other substances to cause gas or fermentation, Knox Gelatine should not be confused with factory-flavored, sugar-laden dessert powders. Knox is 100% pure U.S.P. gelatine. Knox Gelatine has been successfully used in the dietary of convalescents, anorexic, tubercular, diabetic, colitic, and aged patients.

were removed for the relief of hypoglycemia with severe and long continued collateral symptoms of from 1 to 12 years duration. All of the patients recovered from the operation. In 5 of the 6 patients operated upon the blood sugar rose and the collateral symptoms disappeared promptly. In one case the removal of a tumor failed to give improvement, but at a second operation one month later another tumor was found and removed, which resulted in prompt recovery of the patient.

The tumors were small, from 4 mm. to 2 cm. in diameter. In the larger tumors there was extensive fibrosis and calcification. Hyaline degeneration was also noted. Structurally they resembled gigantic islets of Langerhans. They duplicated the pattern of normal islets. They arose from the duct epithelium of the gland. According to Bensley and others the duct epithelium of the pancreas is the source of all growth and repair. In the embryo, as shown by Bensley, epithelial buds from the duodenum grow toward the spleen as branching pancreatic ducts. This duct epithelium is totipotent: i.e., at one point it differentiates into acinous cells, at another point into islet cells, and at other points it pushes forward as branching ducts. This property of the duct epithelium is retained throughout life, and upon it depends the remarkable instances of complete regeneration of the pancreas as a whole, as has been observed in the adult rabbit (Grauer). Once differentiated out of the duct epithelium the islets grow by proliferation of their own cells (Bensley).

The islet tumors may be regarded as a reaction of the duct epithelium to a stimulus that has called forth its duct-building and islet-building potencies, leaving the acinous-building potency in abeyance.

The name nesidioblastoma is proposed in order to give specific identification to these tumors as well as to avoid the more cumbersome designation of adenoma of the islets of Langerhans. Selecting the Greek word for islet, the cells which differentiate out of the duct epithelium to build islets may be called nesidioblasts-islet builders, and when they form tumors the latter may be termed nesidioblastoma. As there is some evidence of a diffuse or disseminated proliferation of the islet cells as a possible cause of hypoglycemia, carrying the application of the name further, it would be logical to designate such diffuse proliferation of nesidioblasts nesidioblastosis.

N. W. Jones, Portland.

HARTUNG, C. A. AND WARKANY, J.

Duodenal Ulcer as a Cause of Death in a Case of Meningococcic Meningitis. J. A. M. A., 110:1101, April 2, 1928.

Ulcer of the duodenum frequently occurs in childhood. In early life it usually occurs in the new born suffering from melena neonatorum and in marantic infants. In later childhood ulcer is the result of trauma, burns, nephritis, uremia and infections. Ulcers due to infection include those associated with tuberculosis, syphilis, typhoid, pneumonia, small pox, chicken pox, scarlet fever, diphtheria, measles, erysipelas, pemphigus and appendicitis. It has never been reported, however, in association with meningococcus meningitis. The authors report the case of a negro boy who came under their care. The entrance complaint was pain in the chest and abdomen. The admission temperature was 101.4°. The evening after admission he had a convulsion and the next day the neck became rigid. Kernig's sign was positive, spinal puncture revealed a pressure of 20 mm. and a cell count of 5000 per cubic millimeter. Culture of the spinal fluid was positive for meningococci. The patient was treated with antimeningococcus serum and he appeared to be improving. He suddenly developed slight tremors of the body. A soap-and-water enema was returned with a large amount of soft brown fecal matter. He died within two hours. Autopsy revealed a duodenal ulcer, sections of which showed gram-negative diplococci similar to those found in the meninges.

Francis D. Murphy, Milwaukee.

» » » ANNOUNCEMENT

FOR the medical management of gastric and duodenal ulcers, Colloidal Aluminum Hydroxide has proved strikingly effective . . . in a triple role: (1) By its unusual affinity for the gastric and duodenal mucosa, it provides a protective mechanical barrier against irritation. (2) Its astringent action assists in controlling hematemesis. And most important, (3) its high acid-combining powers fix free acid and prevent digestion of the delicate fibrin of the clot by strong unbuffered gastric juice. With this triple assistance, the healing process is successfully facilitated — without disturbance of the acid-base balance, or evolution of gas, or stimulation of a secondary acid rise.

Authorities, however, have pointed out the rigorous standards to which the product must conform. Colloidal Aluminum Hydroxide (Truesdale), manufactured by special process, has therefore been released to the medical profession in response to a demand for an efficient, highly palatable and thoroughly ethical preparation. By direct titration, using Toepfer's reagent as indicator, it can adsorb and neutralize at least 12 times its volume of N 10 hydrochloric acid in less than 30 minutes.

The excellent clinical results attained both by its oral administration, and by the use of the newly improved Truesdale Drip Apparatus, recommend it for the gastroenterologist's use.

The Process of Intestinal Rotation in the Human Being Illustrated by the Dried Intestines of the Cat

By
E. G. WAKEFIELD, M.D.,* C. STUART WELCH, M.D.†
and
CHARLES W. MAYO, M.D.‡
ROCHESTER, MINNESOTA

FOR the sake of description, rotation of the human intestine during embryonic development has been divided into three stages. Models to illustrate each of these stages of intestinal rotation would necessarily be somewhat diagrammatic. However, we have been able to prepare dried specimens of the intestines of cats by maintaining the desired anatomic relations of the intestines during drying. These aid greatly in visualizing the important steps of the interesting phases of development of the intestines.

In a 7.5 mm. human embryo the umbilical loop of the intestine has been formed and is herniated into the umbilical cord. Herniation into the umbilical cord is the result of intra-abdominal pressure and the increasing length of the intestine. Examination of the contents of the umbilical hernia shows that the small intestine from the jejunum to the proximal colon is contained in the umbilical cord. This section of the intestines is freely movable on its dorsal primitive mesentery, as shown by the first specimen on the left in Fig. 1. This specimen shows a fixation of the duodenum and colon, which is the result of shortening and thickening of the mesentery at these points. The duodenum and colon are thus brought into close approximation. This approximation is known as the duo-

Fig. 1. Duodenocolic isthmus and first stage of intestinal rotation.

denocolic isthmus. It is about this point that intestinal rotation normally takes place or abnormally fails. In order to understand intestinal rotation, the relations of the duodenum and colon at the extremities of these

mesenteric fixations must be closely visualized at each stage of development. The center specimen in Fig. 1 is a ventral view of the first specimen.

By the time the embryo is 10 mm. in length, the umbilical loop has turned about 90 degrees counter-clockwise from a sagittal to a horizontal plane. This

Fig. 2. Second stage of intestinal rotation.

turning of 90 degrees accomplishes an important phase of rotation which is designated as the first stage of rotation. In this specimen, the cecum and proximal colon are ventral to the duodenum before rotation, whereas, in the specimen on the right, the proximal portion of the colon and the cecum are now on the same level as the duodenum and proximal portion of the jejunum and in a horizontal plane, which now is the plane of the duodenocolic isthmus.

In the second stage of rotation the intestine returns to the abdomen. The mechanism of this return is purely physical, and the intestine is literally sucked back into the abdomen. There are a decrease in the rate of growth of the liver, an increase in the resistance in the umbilical hernia, which is caused by the ever enlarging intestine, pressure of the amniotic fluid outside the hernial sac and a collapse of the lower part of the abdominal wall, all of which combine to produce the "sucking-back" process.

In this stage it is obviously impossible for the intestine to return en masse. The best evidence favors the view that the jejunum (specimen on the left in Fig. 2) begins to pass back and is followed by the ileum and, finally, by the colon. Mall observed that the small intestine is back in the abdomen while the colon and the terminal portion of the ileum are still in

Fig. 1. X-ray appearance of stomach and duodenum. Note the deformity in the pyloric region and duodenal bulb. (Case No. 1)

which will undoubtedly have a far-reaching effect on our present concept of the diagnosis, prognosis and treatment of gastric disease.

The revelations of gastroscopic studies have been increasingly enlightening in various diseases of the stomach, but probably the most noteworthy contributions have been in the diagnosis of gastritis.

For years, chronic gastritis has been cloaked in mystery; accepted by some and denied by others as being a true pathological condition. In the past some of our standard medical text-books have either relegated it to a place of insignificance or ignored it entirely.

Today, however, to deny the existence of chronic gastritis as a definite disease entity would be as erroneous as stating that gastric ulcer or gastric carcinoma did not exist. The work of Hurst (3), Schindler and Ortmyer (4), Faber (5), Konjetzny (6) and others proves conclusively that chronic gastritis must be added to our nomenclature of gastric disease. Eusterman (7), in a recent publication on the Gastritis Problem presents conclusively established cases of gastritis, in which the diagnoses were confirmed at necropsy by histologic examination of surgically excised or resected tissue or by combined clinical and gastroscopic, or by roentgenologic findings. An interesting aspect of his report deals with ten cases of sub-acute or chronic gastritis in which operation was performed. The pre-operative studies of the stomach indicated organic disease such as polyps, ulcer or carcinoma; yet the operative and histologic data disclosed only sub-acute or chronic gastritis. In his report there is no evidence to indicate that these patients had been gastroscoped before operation, and Eusterman concludes that, obviously, the solution of the gastritis problem depends chiefly on gastroscopy.

There were many classifications of gastritis before the advent of gastroscopic studies, but since then, the simplest scientific arrangement has been proposed by Schindler (4) who divides chronic gastritis into four groups: 1—Superficial; 2—Hypertrophic; 3—Atrophic; 4—Post-operative.

The gastroscopic appearance of these various types of chronic gastritis has been fully described in previous communications by Schindler and others.

Gastroscopically, it has been observed that there is a close relationship between atrophic gastritis, pernicious anemia, polypoid and malignant lesions of the stomach. It is not uncommon to find atrophic gastritis and polyps in cases of pernicious anemia, and the malignant degeneration of polyps is not infrequent. In cases of pernicious anemia, with atrophic gastritis, Jones, Benedict and Hampton (8) have observed gastroscopically a regeneration of the mucosa after adequate liver therapy.

Turning to the problem of gastric ulcer and its generally conceded tendency to become malignant, we are again confronted with inconsistent evidence. Data based upon voluminous statistics obtained from large clinics would indicate that five to as high as thirty-five per cent of gastric ulcers become malignant. Where can one find solace in this morbidity? The most comforting answer to this question would seem to be found in Schindler's (9) gastroscopic observations of gastric ulcer. In over one hundred cases of true gastric ulcer he has not observed one to become malignant.

From the standpoint of differential diagnosis we have unhesitatingly employed gastroscopy whenever indicated (10). The presentation of three cases with unusual aspects seems justified in an attempt to stimulate greater interest in this relatively new field of objective science.

Case 1. Mr. C. D., a real estate broker, forty-two years of age, referred by Dr. Sidney Cousins, complained of a gnawing epigastric pain. The pain occurred about one hour after meals and had been recurring intermittently for fourteen years. Food or alkali had given immediate, though temporary, relief. There had been some nausea and vomiting of blood. There was anorexia and weakness but no weight loss. Physical examination revealed under-nutrition of eighteen pounds. Gastric analysis—free HCl 50°, total acidity 70°, Wasserman and Kahn test negative. He brought with him the following roentgenologic report (Fig. 1).

Fig. 2. Showing circumscribed area of rarefaction in the duodenal cap. (Case No. 2)

Fig. 3. Re-examination of stomach and duodenum showing absence of area of rarefaction in the duodenal cap. (Case No. 2)

"The stomach shows very marked hyperperistalsis and there is a large deforming lesion of the pyloric region involving both the pylorus and cap, which does not produce obstruction. This is probably due to an ulcer, but lues and early malignancy must be considered. It is suggested that the stomach be re-examined in a brief period." One week later, we have the following report: "Re-examination of the stomach shows a definite ulcer of the duodenal cap. There is an inflexible infiltration along the greater and lesser curvatures of the pylorus for a distance of about three centimeters. This may be due to scar tissue, but the possibility of an early malignancy is great enough that an exploratory operation is advised." At gastroscopy ten days later the following was observed: "The antrum was best seen in the four o'clock position, which was most unusual, indicating that the pylorus was not free to fall anteriorly. This unusual lack of mobility probably signifies a fixation of the pylorus or duodenum by peri-pyloric adhesions. No peristalsis was observed in the antrum. Distal to the musculus sphincter antri on the greater curvature was a fairly good sized bolus of thick grayish white tenacious mucus. This pathological mucus was adherent in spots to the antral mucosa near the pylorus, but with each respiration it seemed to separate in web-like fashion. There was another small fleck of yellowish-white mucus adherent to the musculus sphincter antri. At first it gave the impression of a little deeper shade than that normally seen. The mucosa appeared to be more edematous than hypertrophied and, at times, had some aspects of stalactites, but not true polypoid in character. This left no

Fig. 4. Appearance of duodenal cap eleven days after first examination. (Case No. 2)

doubt that a moderate degree of superficial gastritis of the antrum was present. No new growth could be observed. Proximal to the angulus there appeared to be a cup-shaped depression of the mucosa which may have represented some redundancy of the mucosa in this area, but not a true diverticulum. This could account for the slight out-pouching seen on the lesser curvature with the X-ray. In the mucus lake no bloody mucus was observed, but most of it was of a moderately thick consistency containing bubbles.

Gastroscopic Impression: Peri-pyloric and peri-duodenal adhesions preventing proper rotation anteriorly of the stomach with the patient in the left lateral position. Superficial gastritis of the antrum." On the basis of this report, the patient was not subjected to operation but treated medically for duodenal ulcer. A communication discloses that this patient has entirely recovered.

Case 2. Mrs. W. T., twenty-eight years of age, housewife. Referred by Dr. Karl Corley. On May 1, 1937, the patient had several tarry stools and complained of weakness and dizziness. The physical examination was negative except for generalized pallor. Haemoglobin was 51% and R.B.C.'s 2,700,000. The surgical consultant made a provisional diagnosis of duodenal ulcer, Meckel's diverticulum, or carcinoma or benign tumor of the cecum. On May 10, ten days later, the first X-ray report was as follows: (Fig. 2) "The esophagus and stomach are normal. There is a circumscribed area of rarefaction in the duodenal cap, which suggests a benign lesion, probably polyp." Two days later: (Fig. 3) "Re-examination of the stomach and cap shows no evidence of abnormality of the cap, but duodenal polypi have their origin in the mucous membrane of the stomach and may protrude through the pyloric sphincter or may not, which accounts for its appearance at one examination and not at another." From this report it was evident that surgical exploration was indicated, but before this was done, gastroscopy was requested. The gastroscopic report was as follows: "The antrum was well seen and the pyloric opening was easily identified. The mucosa appeared normal in all respects.

Fig. 5. X-ray appearance of stomach and duodenum. (Case No. 3)

There was no abnormality in the body of the stomach or in the fundus." One week later the patient was re-examined with the X-ray by another roentgenologist who reported as follows: (Fig. 4) "Fluoroscopic examination of the stomach is negative. The duodenal bulb is regular. There is a slight irregularity of the second portion of the duodenum. The possibility of this being an ulcer should be considered." The patient apparently has recovered. The final diagnosis was not verified by operation, but it is presumed that she was suffering from hemorrhage from a duodenal ulcer.

Case 3. Mr. C. P., fifty-five years of age, carpenter by occupation. Admitted to Emergency Hospital March 29, 1937. This patient gave a two-year history of intermittent severe epigastric pain following the taking of food. There was slight loss of weight and strength. The physical examination was essentially negative. The abdomen was flat and soft without masses or tenderness. Haemoglobin was 54%, R.B.C.'s 2,940,000. Gastric analysis, without using the Alcohol test meal and Histamine, revealed absence of free HCl and a total acid of 35, with microscopic blood present. Examination of the feces, using the Benzidine Test for occult blood, was positive ++. The X-ray report was as follows: (Fig. 5) "Fluoroscopic examination of the chest and esophagus negative. There is no evidence of disease of the stomach or duodenum. There is a sensory resistance just below the greater curvature which was very suggestive of a lesion of the pancreas." Fifteen days

after admission to the hospital the patient was discharged with the following working diagnosis: possible carcinoma of the stomach, possible carcinoma of the pancreas, possible peptic ulcer. Ten days later, April 22, 1937, the patient was re-admitted to the hospital for gastroscopy which revealed a rather large friable hemorrhagic carcinoma on the anterior wall and greater curvature of the stomach. One week later abdominal operation was performed and an inoperable malignant mass was found on the anterior wall and greater curvature of the stomach. Nineteen days later the patient died. At necropsy a section of the mass revealed an adenocarcinoma, grade three, papillary type.

COMMENT

From these case reports one would naturally assume that one method of study was more decisive than the other. However, this is the exception rather than the rule as X-ray and gastroscopy should supplement each other and should not be viewed as competitive branches of science. This is especially true where there is a divergence of opinion as to the differential diagnosis. I would, furthermore, caution against over-enthusiasm in this new field of observation, as only by a conservative attitude and careful study of each case, together with accurate correlation of all data obtained, can the merit and value of gastroscopy be appreciated.

A Simple Test for Determining the Presence of Gastro-Intestinal Lesions A Preliminary Report

By

EDWARD E. WOLDMAN, M.D.*
CLEVELAND, OHIO

THERE are a good many occasions when the physician feels the need of a simple test to determine the presence or absence of a gastro-intestinal lesion. The patient may be so ill that roentgenographic study is impossible or contraindicated because of bleeding or possible perforation. In instances in which radiograms can be made, the evidence they furnish is not always conclusive, for healed lesions with scar formation, or deformities due to a spastic duodenum can not always be distinguished from active lesions. The availability of a simple procedure of this type would also aid in differentiating between organic and functional disease of the gastro-intestinal tract, and between gastro-intestinal disease and diseases outside the digestive system which display symptoms referable to the stomach or intestine.

It was the inability of the roentgenologist to state positively whether the deformity observable in the roentgenogram of a patient who had received treatment for peptic ulcer indicated a healed or an active

lesion which recently led me to search for a procedure which might give more accurate information in these doubtful cases.

It seemed rational to assume that a non-toxic substance which is not normally absorbed through the mucous membrane of the digestive tract, but which might enter the circulation through any break in the mucosa with eventual excretion in the urine, would be suitable for this purpose.

After preliminary investigation, it appeared that phenolphthalein might prove of value in such studies. This drug has been used widely as a mild laxative, and has been the subject of experimental investigation by numerous workers. All of these are agreed that practically 90 per cent of the phenolphthalein is excreted almost immediately with the feces. Vamossy (1) believes that the small quantity of phenolphthalein absorbed is converted into a conjugate, probably a sulpho-compound. In a series of 650 cases in which a small medicinal dose of phenolphthalein has been taken by mouth, Fantus and Dyniewicz (2) have found that free phenolphthalein is generally absent in the urine,

*Visitant, Department of Medicine, St. Luke's Hospital. (From the Department of Gastro-Enterology).

but that conjugate phenolphthalein is always present. They also observed that with larger doses, a greater proportion of patients display free phenolphthalein in the urine, and the quantity of conjugate phenolphthalein is correspondingly increased. Abel and Rowntree

(3) showed that phenolphthalein is not absorbed by the small intestine in dogs, but that there was evidence of slight absorption by the large intestine.

Since phenolphthalein is widely used as a chemical indicator, its detection in the urine, even in minute quantities, is a very simple procedure. Phenolphthalein produces a pink or red color in alkaline solutions, and hence its presence, in dilutions as high as one to ten millions, is plainly shown by the addition of alkali to the urine.

Phenolphthalein is non-toxic, even in large doses, and there is no other contraindication for its use. The few untoward reactions which have been reported have been of allergic type in hypersensitive individuals (4, 1).

For the purposes of this test, it is advisable to administer the phenolphthalein in solution, and in a quantity small enough not to produce a laxative effect, nor to be capable of detection in the urine of normal individuals. Phenolphthalein is not soluble in water, but is readily dissolved in 95 per cent alcohol (5). Even if the alcohol is slightly diluted with water, it will stay in solution, but it will precipitate out in a 20 per cent alcohol-water mixture. For this test, 1 gram of white phenolphthalein is dissolved in 100 c.c. of 95 per cent alcohol. The dose administered is 10 c.c. of this solution, or 0.1 gram of phenolphthalein.

The procedure is as follows: The patient drinks 10 c.c. of the 1 per cent solution of phenolphthalein in alcohol, diluted to 30 c.c. by the addition of water. The water is added to give a larger volume of liquid in the stomach, and to make the solution more palatable, by reducing the strength of the alcohol. The solution should be administered in the morning, when the patient is in a fasting state, because food may prevent the solution from reaching the lesion in the gastro-intestinal mucosa. If the stomach is full of water, the solution might become too dilute, or the phenolphthalein might precipitate out, and hence not reach the break in the mucous membrane. The patient is instructed not to eat or drink for one hour after taking the phenolphthalein.

Specimens of urine are obtained two and four hours

after the patient has taken the phenolphthalein solution. In some instances a six-hour specimen may also be necessary, in case the patient has some condition which may delay the appearance of the drug, such as acute or chronic nephritis, cardiac failure, fever or dehydration.

A portion of each specimen of urine is poured into two containers, one to be used for comparison of color with the other portion, to which 10 per cent sodium hydroxide solution is added. The best containers for the specimens are white porcelain evaporating dishes or small beakers placed on white paper. Test tubes are not satisfactory for these color comparisons, for there is not enough depth to the fluid in them to bring out the color. The 10 per cent solution of sodium hydroxide is added with a dropper until no more change in color takes place. Occasionally a precipitate is formed when the alkali is added, because of the presence of earthy phosphates which are insoluble in alkaline solution.

The urine must be examined promptly, for otherwise false positives may be obtained. As Fantus and Dynciewicz (2) have shown, conjugate phenolphthalein is always present in the urine of a person who has taken phenolphthalein. This does not yield a pink color on the addition of alkali, but if the urine is allowed to stand, some chemical action takes place, probably through bacterial activity, which liberates free phenolphthalein and produces the characteristic reaction.

The test should not be repeated for several days, as phenolphthalein can be detected in some instances forty-eight or seventy-two hours after ingestion. If a

repetition of the test is desired, a specimen of urine should be tested before an additional quantity of phenolphthalein is administered.

CLINICAL STUDY

It was necessary to prove that the phenolphthalein does actually pass into the circulation through any break in the continuity of the mucous membrane, because of an ulcer or a malignant growth, and then is excreted with the urine in sufficient quantity to be

detectable on the addition of sodium hydroxide solution. We had an opportunity to demonstrate this on a patient who had a carcinoma in his mouth on the lower jaw. A piece of cotton was saturated with the solution of phenolphthalein and placed on the lesion in his mouth for one hour. The patient was instructed not to swallow any of the solution. Phenolphthalein was present in the urine at the end of four hours. A normal person who had no break in the mucous membrane in the mouth was subjected to the same test, without any evidence of phenolphthalein in the urine at the end of four hours. Several days later, the patient with the carcinoma in his mouth was asked to drink the phenolphthalein solution through a straw so that it would not come in contact with the lesion. The urine was examined two and four hours afterward, and no evidence of phenolphthalein was found.

This test has been performed on 112 subjects. Seventy-seven were individuals who had no apparent gastro-intestinal lesion, and thirty-five had gastro-intestinal lesions demonstrated roentgenologically or by other means.

Of the 35 patients with lesions, all but one showed a positive test for phenolphthalein in the urine (Table I). In the exceptional instance, there was radiographic evidence of an irregular duodenal cap, and the patient had pain one-half hour after meals which was relieved by food but not by alkalis. Since the last finding is atypical for duodenal ulcer, the patient may not have had an active lesion. The case is listed with the cases of gastro-intestinal disease, because of the roentgenographic picture.

Of the 77 cases with no apparent gastro-intestinal lesion, 75 exhibited no evidence of phenolphthalein in the urine after two and four hours. Two patients in this group displayed free phenolphthalein in the urine (Table II). This control series included 31 normal persons in good health (internes, nurses and colleagues) and 46 patients, both ambulatory and hospitalized, who had some disease other than that of the gastro-intestinal tract. The hospital patients were used because it was felt that they would furnish data which could be compared fairly with those obtained in the group of patients with peptic ulcer or carcinoma of the gastro-intestinal tract. The two patients in this control group in whom tests for free phenolphthalein in the urine were positive were both too ill to check thoroughly for the presence or absence of a gastro-intestinal lesion. One had advanced multiple sclerosis, and the other coronary thrombosis. The latter died a few days after the test was made, but post-mortem examination was refused. It is possible, of course, that these patients may have had some lesion in the stomach or intestines which was not suspected or was masked on account of the other disease present, but this has not been proved.

Several cases in this study deserve special comment. One patient, F. H., male, aged 62 years, had a mass in his epigastrium. The roentgenologist's diagnosis was "retroperitoneal tumor probably in the pancreas, which causes a pressure defect on the lesser curvature of the stomach." In this case, the phenolphthalein test was strongly positive. The patient died and a post-mortem examination revealed an adenocarcinoma of the stomach.

Another man, J. L., aged 60 years, was in the hospital with a carotid sinus syndrome. A very poor history

was obtained because of the patient's inability to speak English. The phenolphthalein test was positive. After this, he was sent to the X-ray department for gastro-intestinal study, where a diagnosis of duodenal ulcer was made, confirming the results of the phenolphthalein test in a patient in whom a gastro-intestinal lesion had been unsuspected.

A patient of Dr. E. D. Cumming, G. W., female, aged 56 years, had an hour-glass stomach which was thought to be due to an ulcerative lesion caused by either a gastric ulcer or a gastric carcinoma. The phenolphthalein test was negative after two hours, four hours and six hours. The following day an exploratory laparotomy revealed a fibrous band which encircled the stomach causing a marked constriction. This band was cut and the constriction immediately disappeared. No evidence was found of an ulcer or carcinoma.

Many urine specimens which contained no free phenolphthalein at the end of four hours, did show its presence after standing 24 hours. This no doubt was due to the splitting off of free phenolphthalein from the conjugate form. Additional evidence of this reaction was observed in several other specimens in which a pink color was obtained on the addition of a 10 per cent solution of sodium hydroxide at the end of the test period, but yielded a deep red color with alkali after standing 24 hours.

In the series of tests here described, only qualitative estimations have been recorded, which seems to indicate, in a small series, a high degree of reliability in determining the presence or absence of a lesion in the gastro-intestinal tract. At the present time, more extended studies are in process to attempt quantitative estimations, since there is some evidence that the quantity of phenolphthalein excreted may have a relation to the size of the lesion. These studies will be the subject of a later report.

SUMMARY AND CONCLUSIONS

A simple test is described for determining the presence of a break in the continuity of the gastro-intestinal mucous membrane. This is accomplished by the administration of 0.1 gram of phenolphthalein in alcohol solution, which is easily detectable, if present in the urine, by the addition of 10 per cent sodium hydroxide two or four hours after ingestion of the test solution. If the test is positive for free phenolphthalein, a break in the mucous membrane of the gastro-intestinal tract caused by ulcer or carcinoma is indicated. If the test is negative, it indicates that the mucous membrane is intact.

In a series of 112 cases, the possible error has been less than 3 per cent both for positive and negative findings.

The reliability of the test depends on the small quantity of phenolphthalein used, and prompt examination of the urine specimens. If these conditions are disregarded, false positives may be obtained.

Phenolphthalein is an ideal drug for this purpose because it is non-toxic, is easily taken by any patient in the small quantity required, and without laxative effect, and the technic for its qualitative estimation in the urine is extremely simple.

The test has a wide field of usefulness in those cases in which roentgenographic evidence is of doubtful authenticity, in differentiating between functional and

organic disease, and in ruling out organic lesions of the gastro-intestinal tract in diseases which may have symptoms referable to the digestive system.

WHILE choline has no effect (1), some of its esters have pronounced effects on gastric secretion. Surprisingly, the results of various investigators are widely diverging. In 1930, Allodi (2) and Reggiani (3, with a test meal) found that acetylcholine (a.c.) raised gastric secretions. Bagnaresi in 1931 (4) reported that a.c. increased volume secretion distinctly and acid secretion less markedly. Faroy and Deron (5) stated that unlike histamine, a.c. when injected daily for prolonged periods, eventually raised the secretion of acid in clinical cases of an- and hypo-acidity, and recommended a.c. for the treatment of these conditions.

In 1932, Wilkinson (6) reported that a.c. when given with a test meal raised the secretion of free HCl in normal human subjects. In 1933, Abbott (7) found increased free acidity in 6 out of 9 normal human subjects and in some patients with achlorhydria following a test meal and acetylbetamethylcholine chloride (a.m.c.). Gebhardt and Klein (8)

tory observed increased acid secretion with a.m.c. and Destree (12) made the same observation with carbaminylcholin (dogs). Recently Schnedorf and Ivy (13) reported that a.m.c. induced acid secretion of the stomach of monkeys refractory to histamine. In most of the tests referred to above, the choline esters were given subcutaneously but in some, intravenously or, in larger doses, per os; one experimenter gave a.c. in suppositories, besides (8).

Our experiments were begun in 1935 before we knew of Myerson's work, and the results presented below tend to explain the divergence of results in this field.

METHODS

Five dogs with Heidenhain pouches were employed. Four were males and one was a female; their body weight ranged between 12 and 20 kg. All of them were in excellent health. The animals were fasted for 24 hours before the tests. The human subjects were normal adults, without gastro-intestinal or other complaints. They fasted for 14 hours before the tests. Levine tubes were passed through the mouth and the stomach contents were aspirated, measured, and all but 10 c.c. returned into the stomach, except in the case of the first aspiration, which was not reinjected. All drugs were given subcutaneously.* Free and total acid were titrated against dimethylaminoazobenzene (method of Michaelis), and phenolphthalein, using n/10 NaOH; acidity is expressed in clinical units, (i.e., cems. of n/10 NaOH required to neutralize 100 cems. of gastric juice). Peptic activity was estimated by the modified Mett method and expressed as the product of Mett units and volume of secretion (14).

RESULTS

I. On Dogs.

The data in Table I prove that a.c. chloride, a.c. iodide, a.m.c. chloride and prostigmine definitely raise the acid secretion of the Heidenhain pouch.

A. Acetylcholine (Chart 1).

A.C. is the weakest stimulant among the drugs employed; 100 mgm. had very little effect (expt. No. 1) but 400 mgm. induced distinct rises of volume and

published that a.c. raised the acid secretion of the stomach in only a few of their normal subjects. In 1935, Ferguson and Smith (9) reported that, following a test meal, small doses of a.m.c. increased and larger doses of a.m.c. diminished the secretion of free acid in monkeys. In 1936, Myerson, Rinkel and Dameshek (10) published their results on patients with dementia praecox. Using a.m.c. they found decrease or disappearance of gastric acid secretion and even acid deficit. In 1937, Gray (11) from Ivy's labora-

acidity (expt. No. 2). The effect lasted for 60 minutes after the injection. Repeated injections of 10-100 mg. of a.c. given every 10 minutes (except in expt. No. 9, every 30 minutes) regularly evoked considerable secretion of acid (expts. 3-9, and Chart 1). In the case of a single dose, the maximum effect of the drug was at-

tained 30 minutes after injection and with repeated doses (which individually were, of course, smaller than the single doses) 30-90 minutes after the beginning of injections. In some experiments two peaks were observed (No. 8 and 9). In one experiment (No. 6) the increased secretion following the first injection

of a.c. was not maintained, although 20 mgms. of a.c. was injected every 10 minutes, and the values dropped to zero. Generally it can be said that injections of a.c. in repeated doses at regular intervals raised acid secretion considerably, but did not maintain a steady level of secretion as histamine, or a.m.c. frequently do. This is understandable because the effect of histamine and a.m.c. depends essentially on the rate of absorption, while that of a.c. depends both, on the rate of absorption, and the rate of destruction by esterase. In 8 out of 10 experiments the maximum of volume and of acid secretion occurred simultaneously (a 30 minute difference in No. 3 and a 15 minute difference in No. 4). A.C. definitely increased the secretion of pepsin (experiment No. 4). The question whether stomach secretion to a.c. can be maintained without exhaustion of the secretory mechanism has been answered by experiments No. 8 and 9 (see Chart 1). In both experiments secretion remained elevated for 6½ hours with subcutaneous injections of a.c. iodide repeated every 10 and 30 minutes, respectively.

B. Prostigmine and A.C.

Prostigmine (1 mgm.) very definitely raised volume and acid secretion (experiment No. 10). The peak of volume secretion was reached 30 minutes before that of acid secretion. Duration and degree of secretion were considerable when compared to the effects of a.c. and of a.m.c. on the same dog (No. 52).

Since prostigmine delays the destruction of a.c. these two drugs were combined (expts. No. 11 and 12). Because from previous experience on dogs (and from tests on man carried out at present) we knew the potentiating effect of the two drugs (15), very small doses of a.c. were employed. One mgm. of prostigmine

and 50 gammas of a.c. raised volume and acidity of pouch secretion considerably, and the peak values for both were attained simultaneously.

C. Acetylbetamethylcholine chloride (Charts 2-5).

The smallest dose of a.m.c. employed, namely .1 mgm. had no effect (expt. No. 13), but doses of .3 mgm. and upward raised volume and acidity of secretion. Repeated doses of a.m.c. had very pronounced effects and all secretions of the stomach rose distinctly (expts. No. 14, 15, 19 and 24). There is an interesting difference between the effect of a.c. and that of a.m.c. While with a.c. the maximum secretion of fluid and of acid was attained simultaneously in most experiments, a dissociation of the two was observed in the case of a.m.c. (see Table I and Charts 2-5). In nine out of eleven experiments volume secretion reached its maximum earlier than acid secretion. The retardation of the peak of acid secretion varied between 15 and 150 minutes, but was 30 minutes in 7 out of 9 experiments. Since the gastric secretion was collected every 20 minutes, the dissociation must have taken place during this period; a few observations showed that the peak of volume secretion was attained at the beginning of this period. No clear relationship was found between the dose of a.m.c. and this phenomenon.

Do increasing doses of a.m.c. depress the secretion of the pouch as described by Gray (11)? In order to answer this question the results with a.m.c. in Table I have been grouped according to individual dogs. Comparing the results for total acidity in each dog we notice that it rises definitely with increasing doses of

a.m.c. Comparing the period of time elapsing between injection of a single dose of a.m.c. and the maximum response of acidity we see that the secretion of acid is delayed, or "postponed" by a.m.c., and that this delay is greater with larger doses of a.m.c. (see Charts 2-4). The total secretion of HCl (in mgms.) for a period of 3 hours after the injection of a.m.c. was the following: In dog No. 52, single doses of 0.3, 5.0 and 20.0 mgms. of a.m.c. evoked a secretion of 2.9, 4.2 and 8.4 mgms. of HCl, and in dog No. 12, 0.4, 1.0, 10.0 and 30.0 mgms. of a.m.c. evoked a secretion of 1.2, 1.5, 1.7 and 2.3 mgms. of HCl. Dog No. 12 had an old (two years) and somewhat refractory Heidenhain pouch. These data show that the secretion of HCl by the Heidenhain pouch is greater with larger doses of a.m.c. and that the effect of the larger doses amounts to a delay but not suppression of acid secretion. Chart 5 demonstrates that repeated doses of 1.0 mg. of a.m.c. do not exhaust acid and volume secretion of a pouch over a period of 3 hours (see also expts. No. 14, 15, 19 and 24).

In order to investigate the interaction between choline esters and histamine and pilocarpine, the following experiments were done on Heidenhain pouch dogs:

I. The Effect of A.C. on Pouch Secretion Provoked by Histamine* (Chart 6, Expt. No. 25†).

0.5 mgm. of Histamine was injected subcutaneously every 30 minutes for a period of six hours. Following a control period of 90 minutes, 10 mg. of a.c. were injected subcutaneously every 10 minutes for 90 minutes. From Chart 6 it is evident that the addition of a.c. to histamine raised acid secretion slightly, but fluid secretion to nearly four-fold its control level. It increased also the secretion of pepsin which, as has been shown by Babkin and collaborators, is not stimulated in the dog by histamine, and which had dropped to nearly zero in the control period in which only histamine was injected; this was probably due to the "washing out" effect assumed by Babkin (16). Pepsin secretion rose to nearly 50 units under the influence of a.c. and then dropped to practically zero when histamine alone was continued. Following the cessation of a.c. injection, volume and acidity fell below the control level and recovered gradually towards the end of the experiment. In an identical experiment (No. 26) on

*Ergamine acid phosphate used throughout.
†From here on the experiments are not listed on tables.

dog No. 52, the same results were obtained except that the rise in volume was not so great (from 2.8 to 10.0 ccms.) and that its depression after cessation of a.c. injections was much greater (from 12.4 ccms. to 4.8 ccms. with consequent recovery to 7.0 ccms.).

II. The Effect of Histamine on Pouch Secretion Provoked by A.C. (Chart 7, Expt. No. 27).

In the following the experimental procedure was reversed and the effect of histamine on a secretion provoked and maintained by a.c. was tested. Two such

experiments were made in which 30 and 50 mg. of a.c. respectively were injected subcutaneously every 10 minutes for periods of 5 and 4 hours respectively. Superimposed upon this 0.25 mgm. of histamine was injected every 15 and 10 minutes respectively. The results were essentially the same as in the reverse experiment but the depression of acid secretion following the stopping of histamine injections was more pronounced than in the preceding group of experiments. Volume secretion dropped from the control value of 2.2 ccms. to 0.4 ccms. while the secretion of free acid dropped to zero, although 50 mg. of a.c. were given every 10 minutes (Chart 7, Expt. No. 27). In the other experiment (30 mg. of a.c. every 10 minutes) free acidity dropped from the control level of 70 to 48 C.U.,* total acidity from 100 to 76 C.U., and volume from 0.7 to 0.4 ccms.; 30 minutes later the volume rose to 1.9 ccms. (Expt. No. 28).

III. The Effect of A.C. on Pouch Secretion Provoked by Histamine-Pilocarpine.

Since gastric secretion to a meal corresponds more to the combined effects of histamine and pilocarpine than to the effect of histamine alone (Babkin 16), three experiments were carried out in which 0.5, 0.5 and 1.0 mgm. respectively of histamine plus 0.5 mgm. of pilocarpine† were injected subcutaneously every half hour throughout the entire experiment (Expts. No. 29-31). After a control period, 10 mgms. of a.c. were injected subcutaneously every 10 minutes for 90 minutes, and after that the experiment was continued for approximately four hours with only histamine-pilocarpine. In two experiments the same effects as in the previous group of experiments (histamine without pilocarpine) were noted while in the third experi-

*Clinical units.

†Pilocarpine nitrate was used throughout.

ment volume and acid secretion dropped considerably during and recovered after cessation of a.c. injections.

IV. *The Effect of Pilocarpine on Pouch Secretion
Provoked by A.C. (Chart 8, Expt. No. 321).*

As a control to the above experiments, secretion was provoked by subcutaneous injections of 20 mgms. of a.c. every 10 minutes to which was added, after a control period, 0.5 mgm. of pilocarpine (every 15

minutes). A great increase in the secretion of free acid and a smaller but yet very evident increase of volume and total acidity followed the injection of pilocarpine and continued after its cessation. The experiment was repeated on the same dog, using 30 mgm. of ac and only 0.25 mgm. of pilocarpine with similar but somewhat less pronounced results, probably due to the smaller dose of pilocarpine (Expt. No. 35). It should be noted that injection of pilocarpine raised free acidity and decreased combined acidity, i.e. probably the secretion of mucus, in experiment No. 32 (see Chart 8) was raised.

V.—*The Effect of A.C. on Pouch Secretion Provoked by Pilocarpine.*

In the following experiments the above procedure was reversed. One mgm. of pilocarpine was injected subcutaneously every 30 minutes and after a control period 30 mgms. of a.c. in addition were injected every 10 minutes for a period of 90 minutes (Expt. No. 34). While pilocarpine itself increased volume secretion only, the addition of a.c. raised secretion of volume and of free and total acid considerably. The effect was maintained for 60 minutes after the last injection of a.c. In the same dog the experiment was repeated, using only 0.5 mgm. of pilocarpine and 10 mgm. of a.c. In this experiment a.c. raised only the volume of secretion while free and total acidity were not changed (Expt. No. 35).

VI. *The Effect of A.M.C. on Purch. Selection Pro-*
posed by Hottelmeier (Chart 9, Expt. No. 36).

Histamine 0.5 mm. was injected subcutaneously every 30 minutes for 7 h; after constant acid secretion was established 0.1 mm. of a.m.c. was injected subcutaneously every 10 minutes for 90 minutes. A slight rise of acid secretion and a large rise of volume secretion occurred when a.m.c. was superimposed upon histamine. A marked depression of volume and acid

secretion beginning after the stoppage of a.m.c. injections was followed by slow recovery.

VII. *The Effect of A.M.C. on Pouch Secretion Provoked by Histamine-Pilocarpine (Charts 10 and 11, Expts. 37 and 39).*

In order to complete the picture, a single dose of a.m.c. was superimposed upon the effects of constantly repeated injections of histamine-pilocarpine, 0.5, 5.0 and 20.0 and 30.0 mgms. respectively of a.m.c. were given in four different experiments (No. 37-40, the first three on the same dog), in which active pouch secretion was maintained by injections at 30 minute intervals of 0.5 mgm. of histamine and 0.5 mgm. of pilocarpine. 0.5 mgm. of a.m.c. produced a slight rise

of acidity and a marked rise of volume, both followed by depression and recovery to control levels (Chart 10). 5.0 mgms. of a.m.c. was followed by an immediate drop of acid and volume secretion, the latter being much more marked, with slow recovery to control values; an appreciable intermediary rise of free acidity occurred. 20.0 (Chart 11) and 30.0 mgms. of a.m.c. produced an immediate large drop of volume and acid secretion with slow recovery of fluid secretion and faster recovery of acid secretion to control values.

2. *On Men* (Chart 12, Expt. No. 43-44).

A. *Acetylcholinesterase*.

Two sets of experiments were done on one normal

colored male subject (normal white female) taking one dose of 2 g.-m. In one set the in the next one, followed. A great free acidity dropped to and rose considerably

colored male subject (Expts. No. 41-42), and on one normal white female subject (Expts. No. 43-44) receiving one dose of 20 mgms. a.m.c. in each experiment. In one set the subjects expectorated all saliva, in the next one, done a week later, all saliva was swallowed. A great difference was noted, in so far as free acidity dropped to zero when saliva was swallowed and rose considerably, even in the same experiment,

when it was expectorated. Chart 12 is representative of the results on both persons. The large increase of volume in the second experiment indicates the amount of neutralizing and diluting fluid by swallowed saliva. We realize that in an experiment of longer duration, saliva would act as gastric secretagogue (19). Pepsin secretion was increased by a.m.c.

B. Prostigmine.

After a control period a healthy male subject received a subcutaneous injection of 1 mgm. of prostigmine. All saliva was expectorated. Secretion rose from a control value of 11 ccms. with free acidity of 21 C.U. and total acidity of 38 C.U., to values of 68 ccms. and 43 and 58 C.U. respectively. Peptic activity rose from a control value of 43 Mett units to 173 units. Volume, acidity and peptic activity remained elevated for more than 60 minutes.

DISCUSSION

The question whether a.c., a.m.c. and prostigmine produce an acid or alkaline secretion of the stomach has been definitely answered for the secretion of the Heidenhain pouch and of the normal human subject: a large single dose of a.c. and smaller repeated doses of a.c., small doses (above 0.3 mg.) and larger doses

of a.m.c. (up to 30 mgms.) all produce increased secretion of fluid and of acid by the stomach (subcutaneous injection). Myerson's results on patients (10) in which he obtained alkaline secretion to a.m.e. may be explained by the possible swallowing of much of the saliva, which is secreted so abundantly following injections of choline esters. At least our experiments on human subjects have proved that in the same person a good response of secretion of free and combined acid is obtained when the subject carefully expectorated all saliva, and that when he swallowed it free acid was absent. We realize that our results do not explain why Myerson and collaborators obtained an acid deficit (10), while in our experiments free acidity dropped to zero and some total acid was present. It may be possible, however, that either the salivary or the gastric secretion of the patients employed by the above mentioned group of investigators was different from that of our normal subjects. It seems worth while remarking that Abbot, who found an increase of gastric acid secretion in normal subjects following a.m.c. remarks in his paper that precautions were taken against swallowing of saliva (7, p. 325). In one of Myerson's experiments (10, Chart 3, page 1009), a significant initial rise of free and total acid is apparent after injection of a.m.e.

We confirm Gray's findings (11) of potent stimulation of gastric secretion by small repeated doses of a.m.c. Gray reports that repeated larger doses of a.m.c. (1 mgm.) stimulate the production of a small quantity of an alkaline secretion in dogs with pouches of the whole stomach. Our findings (1 mgm. of a.m.e. given every 30 minutes did not exhaust acid secretion for 3½ hours, see Chart 5 and Table I, No. 24) are not necessarily opposed to his, because we employed Heidenhain pouches. Since it seemed possible, hence, that the alkaline secretion of the pyloric antrum might be increased by a.m.e., we injected one dog with a pyloric pouch (without vagus supply) with 1.0, 3.0 and 5.0 mgms. respectively of a.m.e. subcutaneously (on different days). No increased secretion of the pouch was noted however. Since there are mucus glands in the cardia, fundus and body of the stomach, besides those in the pyloric antrum, the difference between Gray's and our findings cannot be explained at present; besides, it is well conceivable that a whole stomach pouch and a Heidenhain pouch may have different mechanisms of secretion besides a possible difference in mucus production. Other differences between our findings and those of Gray may possibly be explained similarly. Doses of a.m.c. above 1 mg. produced only a small quantity of alkaline secretion in his experiments while we found doses up to 30 mg. (subcutaneously) producing acid secretion of the pouch which in the latter case did not return to control levels 180 minutes after injection (see Table I and Charts 2, 3 and 4).

Large single doses of a.m.c. (up to 30 mgms.) depressed the secretion of a pouch to constantly repeated injections of histamine + pilocarpine, but did not make it refractory to histamine-pilocarpine. For the reasons cited above this finding is not necessarily opposed to that of Gray who, besides, gave repeated injections of 1 mg. of a.m.c. every 10 minutes for two hours and then found the whole stomach pouch refractory to histamine.

Our results with prostigmine on a human subject and on dogs are opposed to those of Myerson and

collaborators (10) on patients. They found that prostigmin produced essentially the same effects on gastric secretion as did a.m.c., i.e. a marked reduction in acidity with increased mucin content; fluid secretion was not changed appreciably. In tests in which physostigmin or prostigmin was followed shortly by a.m.c. they found that prostigmin acted as a synergist to a.m.c. thus enabling small doses of a.m.c. to produce a marked effect in changing the gastric juices from acid to alkaline (10, page 1012). Our experiments (Table I, No. 10-12) on pouch dogs proved to the contrary that prostigmine alone as well as in combination with a.c., effected an unquestionable secretion of fluid, free and total acid, and the experiment on man showed that 1 mg. of prostigmine produced a marked gastric secretion of fluid, pepsin and of acid provided no saliva was swallowed. In view of these findings we would feel reluctant to use these drugs in the treatment of peptic ulcer, as proposed by Myerson, Rinkel and Dameshek (10, p. 1012).

Babkin (16) recommended the use of histamine-pilocarpine for function tests of the stomach, rather than that of histamine only. In view of our results, which demonstrated that a.c. stimulated acid as well as peptic secretion, and that histamine and a.c. act on gastric secretion synergistically, it might be worth while to consider a combination of these two compounds for a function test of the stomach, as well as for the treatment of hypo- and certain an-acidities (see Faroy and Deron, 5). Besides, from the physiological standpoint, a.c. would seem to be a more "normal" stimulus than pilocarpine.

In our experiments with a.m.c. (see Table I) the peak of fluid secretion was attained before that of acid secretion. We have observed the same with histamine frequently, but not regularly. In experiment No. 10 prostigmine acted similarly, but not in combination with a.c. (expts. 11-12). The increase of fluid secretion following a.m.c. usually occurred during the first half hour, and in some experiments we have observed it to begin within 10 minutes after injection.

When comparing results in the same dog it becomes apparent that increasing doses of a.m.c. provoke increased gastric secretory response; but the period of time between injection and onset as well as peak of acid secretion is prolonged with the larger doses of a.m.c.

Histamine (and histamine + pilocarpine) and a.m.c. in small doses (0.5 mgm. subcutaneously) are synergists. Following the synergistic effect a depression of histamine secretion occurs, followed by recovery (see Chart 10). Large doses of a.m.c. depress histamine-pilocarpine secretion temporarily, followed by more or less rapid recovery (see Chart 11). Repeated injections of small doses of a.m.c. (see Chart 9) effected a small rise of acid and a large rise of volume secretion followed by a profound depression of both and slow recovery.

Histamine or histamine-pilocarpine and a.c. are likewise synergists for gastric secretion. In eight experiments in which 10-50 mgms. of a.c. were superimposed

upon histamine stimulated secretion or in which histamine was superimposed upon a.c. stimulated secretion, the output of volume and acid was largely increased, and was depressed upon discontinuation of the superimposed drug, with slow recovery following in most experiments. In only one test did superimposing of a.c. (10 mg. every 10 minutes) depress histamine secretion immediately, with recovery after cessation of a.c. injections.

Pilocarpine does not suppress pouch secretion to a.c. In two experiments pilocarpine superimposed upon a.c. secretion (30 mg. a.c. subcutaneously every 10 minutes) raised volume and acid secretion considerably (see Chart 8). We may therefore say, that a.c. in larger doses raised volume and acid of a pouch secretion produced by pilocarpine. In previous work on man, we have found that pilocarpine decreased gastric secretion of acid (17, see also 1 and 18). We found that in normal persons (but not in ulcer patients) pilocarpine increased secretion of visible mucus. In the Heidenhain pouch pilocarpine seems to be synergistic to a.c. in raising acid secretion. Histamine (or histamine-pilocarpine) and a.c. as well as a.m.c., seem to be synergists when injected together, but a temporary partial exhaustion of the secretory response to one of them becomes apparent when the injection of the second drug is stopped. It must be a peculiar mechanism, worth while of further analysis, by which two gastric secretagogues act as synergists in small doses, followed by secretory depression, when one of them is discontinued. On the other hand a large dose of one drug will suppress a secretion maintained by the other one. A somewhat similar phenomenon has been reported by Alley from Babkin's laboratory (20), in that histamine lowers gastric secretion to sham-feeding and to a meal.

SUMMARY

Acetylcholine increased acid, volume and pepsin secretion of the Heidenhain pouch. It did not exhaust secretion for seven hours, when 50 mgm. of acetylcholine iodide was injected every 10 minutes.

Acetyl-beta-methyl-choline in small and large doses increased acid and volume secretion of the pouch. Large doses effected a preliminary inhibition of secretion followed by a greater secretory response than that to smaller doses.

Acetylcholine and histamine were found to be synergists relative to gastric secretion. A depression of secretion appeared after one of them was discontinued, followed by recovery.

Histamine and small doses of acetyl-beta-methyl-choline acted synergistically on pouch secretion. A depression of secretion and slow recovery followed discontinuation of one of them. Large doses of acetyl-beta-methyl-choline depressed histamine-pilocarpine secretion, but the pouch was not refractory to histamine-pilocarpine. Prostigmine and prostigmine plus acetylcholine produced increased secretion of acid of the Heidenhain pouch.

Acetyl-beta-methyl-choline stimulated gastric secre-

tion of volume, acid, and pepsin in normal subjects. Swallowing of the saliva (plentifully evoked by this drug) lowered free acidity to zero.

Prostigmine stimulated human gastric secretion of fluid and acid. In view of our results regarding the stimulating effects of acetyl-beta-methyl-choline and

prostigmine on the acid secretion of the human stomach, we cannot advise the use of these drugs in the treatment of peptic ulcer as proposed in the literature.

We wish to thank Miss H. Katz and Mr. I. Beylin for technical assistance.

The Takata Reaction in the Blood Serum*

By

EDGAR WAYBURN, M.D.

and

CLIFFORD B. CHERRY, M.D.

SAN FRANCISCO, CALIFORNIA

IN 1925 the Japanese professor Maki Takata introduced a new differential test of the blood serum which he intended for use in the diagnosis of lobar and lobular pneumonia (1). To 1 cc. amounts of dilutions of serum from 1:5 to 1:500 in a medium alkalized by 0.25 cc. 10% Na_2CO_3 he added 0.25 cc. of a mixture of equal parts of 0.5% HgCl_2 and 0.02% basic fuchsin. After ½ hour in a water bath at 15° C. a positive reaction showed precipitation as well as bluish coloration of the supernatant fluid in the dilutions of 1:10 to 1:70 or 1:100. A positive reaction was said to occur in lobar pneumonia and in some cases of tuberculosis of the exudative type. Collaborating with K. Ara, Takata (2) also employed a modification of this test in the spinal fluid: a blue-violet precipitate occurred in central nervous system syphilis, while a rose coloring of the liquid without precipitate occurred in cases of meningitis.

During the past 12 years both tests have been further investigated by a large number of workers. The publications dealing with the spinal fluid fall outside the scope of this paper. In 1929, Staub and Jezler (3) modified the test of the blood serum slightly, failed to corroborate its occurrence in lobar pneumonia but found that changes occurred in the presence of cirrhosis of the liver. Jezler (4, 5, 6) experimented

extensively with the reaction during the next several years. He used a series of 8 tubes each containing 1 cc. of serum diluted with 0.9% NaCl to make concentrations of 1:2 to 1:256. To each tube was added 0.25 cc. Na_2CO_3 and 0.3 ccm. of reagent, consisting of equal parts of 0.5% HgCl_2 and 0.02% aqueous fuchsin. Readings were made immediately, after ½ hour and after 5 hours. For the occurrence of a positive reaction it was necessary for flocculation to appear in at least 3 tubes, the first of which had a concentration of 1:32 or more. Of approximately 1247 cases done, the diagnosis was checked by autopsy in 264. 70% of 176 cases of cirrhosis of the liver yielded a positive reaction. Among 90 cases of cirrhosis confirmed by autopsy, 80% were positive; among 86 cases diagnosed by clinical criteria only, 58% were positive.

Jezler's work has been checked by a number of authors. Most of those who used the test on a large number of cases have corroborated his results, i.e. that strong reactions were obtained in cirrhosis (Table I) and that positive reactions in other diseases were uncommon.

Van Ginkel (7) omitted the use of fuchsin which he did not consider necessary to the reaction, employed dilutions up to 1:128 only. Crane (8) likewise omitted fuchsin and used 1:64 as his highest dilution. Hafström (9) and Schindel and Barth (10), both of whom

*From the Department of Medicine of Stanford University and from the Department of Public Health of the City and County of San Francisco, Cal.
Submitted September 8, 1937.

added basic fuchsin to the reagent solution in their earlier investigations, later agreed that the fuchsin served no purpose.

Rohrer (11) did 125 tests on 108 patients: Among these were 18 positive reactions, 15 of which were in cases of Laennec's cirrhosis; the others included 2

TABLE I

of the liver by various authors*

plain test tubes, allowed to clot, later centrifuged. 1 cc. of serum was removed. 1 cc. of 0.9% NaCl was added to each of 8 Wassermann tubes 1.1 cm. in diameter and 12.5 cm. in length. The serum was pipetted into the first of these and serial geometric dilutions were made from 1:2 to 1:256. The fluid was pipetted

of the type of color change. In general (1) designated a flocculent covering the bottom of the tube, (2) one which attained a height of 1 to 3 mm. and (3) one which was over 3 mm. in height. Thus, a strongly positive result would read 00233210, a more weakly positive 00011100. With very few exceptions there

back and forth 4 to 5 times for each dilution; the final cc. was thrown away. To each tube was added 0.25 cc. of 10% anhydrous Na_2CO_3 , followed by 0.15 cc. of 0.5% HgCl_2 . The entire rack was agitated thoroughly 30 to 40 seconds after the addition of Na_2CO_3 ; the individual tubes were shaken as soon as HgCl_2 was added to each. In a number of duplicate tests done throughout the early stages of the experiment basic fuchsin was mixed with the HgCl_2 and 0.5 c.c. of the resulting reagent was used in place of the HgCl_2 alone, but was found to result in a lesser number of clear-cut positive reactions and more equivocal ones. The tubes were left at room temperature for 24 hours before reading. In a number of cases readings were also made immediately, after several or after 48 hours but none were found to be as good as the 24 hour reading.

A characteristic precipitate occurred in tubes from sera which were considered positive. This was a white to pearl-gray, soft, large-flaked flocculent. In order that a given sera be considered positive it was necessary for this type of precipitate to occur in at least 3 consecutive tubes. In actuality this began in the dilutions of 1:8 to 1:16. The appearance of a fine granular, usually brick red precipitate was common in the highest dilutions and of no significance. Indeed the use of only 6 tubes as advocated by Crane is rational, although we believe that the results can be shown more clearly with 8. The readings were recorded after the form of the Lange colloidal gold test, the amount of precipitate present being used as the index instead

was no difficulty at all in the readings; this became more apparent as our familiarity with the technique increased. Fig. 1 shows a result of the strongly positive type (from patient B—who had cirrhosis of the liver); Fig. 2 shows the same test after being shaken. (00023332)

RESULTS

The detailed results of the Takata reaction in all types of disease are shown in Table III. The majority of the diagnoses are clinical, but particular effort was made to check up the results of the test in the autopsy material.* There was a total of 94 cases of portal cirrhosis of the liver, 79 of these being considered in the advanced and 15 in the early stages of the disease. The criteria of advanced cirrhosis were emaciation, ascites, marked anemia, hemorrhage, variable icterus, spider hemangiomas, collateral circulation, changes in the carbohydrate metabolism, a hard liver, either large or small, known presence of the disease for some time, incapability of clinical improvement, rapid progress to exitus. The cases designated as early were in better physical condition, had hard livers, usually moderately enlarged, slight or no anemia, slight or no evidence of bleeding, no X-ray evidence of esophageal varices, few or no spider hemangiomas, little urobilin in the urine, and usually improved under treatment in the hospital. Among the advanced cirrhotics there

*We express our appreciation to Dr. Alvin Cox of the Stanford University Department of Pathology for his assistance in judging the pathological material and to Miss Anna Hall for valuable technical assistance.

Fig. 1

were 73 positive and 6 negative reactions, a total of 92.4% of positive reactions. Among 35 advanced cirrhoses proven by autopsy there was a positive reaction in 100%. Of 2 early cirrhoses checked by necropsy, on the other hand, 1 gave a negative reaction. The cases diagnosed clinically only as early cirrhosis, however, were all positive, making a total of 14 out of 15 positive reactions or 93.3% which is a figure essentially the same as that obtained in the more advanced cases. There were, very possibly some cases in which some pathological evidence of cirrhosis may have been present in which no clinical diagnosis of cirrhosis was made and the Takata reaction still negative, but it is noteworthy that among 142 autopsies on tested patients there was only 1.

There were 5 cases in which the diagnosis of acute yellow atrophy was made: 4 of these died, all coming to autopsy; 1 recovered. This latter case clinically and 1 other, in which pathological proof was found, had also underlying cirrhosis. Both of these had strongly positive Takata reactions. Another case with a positive reaction (00033320) showed pathologically extensive toxic necrosis of the liver. The other 2 showed no pathological evidence of cirrhosis and both had repeated completely negative Takata reactions (00000000).

There were a number of conditions in which there

Fig. 2

was intrinsic involvement of the liver without the presence of portal cirrhosis; in almost all of these cases the diagnosis was confirmed by or made by autopsy: 1 case of portal thrombosis with multiple liver abscesses gave 00331100 while 3 cases of liver abscesses without portal thrombosis were all negative (00000000). 3 cases of Banti's syndrome and 2 of splenic and portal thrombosis gave consistently negative results. There were 3 cases with extensive cholangitis followed by irregular increase of the peri-portal connective tissue. In none of these was there a positive Takata reaction. There were 4 cases, 3 pathologically proven, of tuberculosis of the liver without cirrhotic changes, 3 of which gave negative Takata reactions and 1 a positive (00012200). 1 case with both tuberculosis and cirrhosis had a positive Takata reaction (00111000).

In the group designated acute hepatitis are included the cases of simple catarrhal jaundice, cases with jaundice following the administration of heavy metals, notably arsphenamine, and a few apparently more severe cases of jaundice indistinguishable in onset from catarrhal jaundice but more severe in their course. Among 24 cases in this group there were 2 positive reactions, both having the weakest type of positive, 00011100.

There were 20 cases of cholecystitis and cholelithiasis, all of which were uniformly negative (00000000). 1 case of gumma of the liver and 2 cases of hemolytic jaundice were likewise negative.

There were 37 cases of primary and secondary carcinomatous invasion of the liver: 4 of these were primary in the stomach, 10 in the pancreas, 3 in the gall bladder, 1 in the intrahepatic bile ducts, 1 in the ampulla of Vater and 18 elsewhere. All gave uniformly negative reactions with 1 exception. This case, clinically diagnosed as carcinoma of the breast, showed a Takata reaction of 02333000. At autopsy there was found widespread growth of carcinoma associated with proliferation of dense fibrous tissue in the region of the portal spaces.

Among the diseases with chief involvement outside the biliary tract cardiac decompensation from various causes with accompanying passive congestion of the liver ranks first. There were 122 cases in this group with 9 positive reactions or 7.4%. In practically all of these the decompensation was of considerable degree and duration. In 1 case in which there was improvement of the decompensation the Takata reaction became negative with the change in the clinical condition.

Pneumonia is mentioned with particular interest inasmuch as the test was first used to differentiate between the lobar and lobular types of pneumonia. In this series there were 31 lobular pneumonias with no positive reactions and 24 lobar pneumonias with 2 positive reactions (00233100) during the acute febrile stage of the disease. 1 of these patients died of pneumonia without autopsy. The other, two months later, was entirely negative and then again became positive (00012220). This patient had long standing Graves' disease.

There were 58 cases of pulmonary tuberculosis without cirrhosis of the liver. Of these 3 were positive, 2 having had thoracoplasty and a chronic course and 1 a history of cholecystitis.

Occasional positive reactions were found in miscellaneous diseases. These were mostly of the weak

variety: They included 1 out of 7 cases of subacute bacterial endocarditis and 1 out of 5 of lung abscess. There were 3 cases of acute glomerular nephritis and 1 acute flare up of chronic glomerular nephritis, all of which gave positive reactions. All of 24 other cases of chronic glomerular nephritis gave negative reactions.

Finally, there were 5 other instances in which a transient positive reaction appeared: A case of leprosy with artificially induced hyperpyrexia; 1 out of 21 cases of diabetes—this reaction occurred while the patient was in coma, disappeared with his emergence (although diabetes was still present); 1 case of ulcerative colitis; 1 out of 4 cases of exfoliative dermatitis, (a follow-up two years later showed this man without dermatitis, with a firm, slightly large liver and a Takata reaction of 00000000); and 1 case of inguinal hernia during strangulation. The remainder of the cases were entirely negative in their reaction. These include the following:

Chronic alcoholism 90 (including 18 fatty alcoholic livers, 51 chronic alcoholism, 21 pellagra and peripheral neuritis), arteriosclerosis 9, hypertensive vascular disease 7, coronary thrombosis 23, bronchial asthma 3, pneumoconiosis 2, upper respiratory infection 11, pleurisy with effusion 11, empyema 6, pharyngitis 2, tonsillitis 3, sinusitis 3, Graves' disease 12, peptic ulcer 50, duodenal diverticulum 4, acute appendicitis 7, pancreatitis 3, tuberculous peritonitis 2, miscellaneous carcinomata without liver metastases 28, normal pregnancy 2, toxemia of pregnancy 43, incomplete abortion 4, pyelitis 5, hypertrophied prostate 2, pelvic inflammatory disease 13, gonorrheal urethritis 4, urethral stricture 2, central nervous system syphilis 13, psychoneurosis 6, cerebral thrombosis 12, meningitis 5, osteomyelitis 2, fractured ribs 3, fractured jaw 2, sacro-iliac slip 3, head injury 3, arthritis 10, pernicious anemia 6, myelogenous leukemia 7, lymphoblastoma 6, anemia (not classified) 4, gangrene

TABLE III
The Takata reaction
Results of mercuric chloride test in 1025 cases

Diagnosis	All Cases (Clinical and Autopsy Diagnoses)			Cases Proven by Autopsy		
	Number	Positive	Negative	Number	Positive	Negative
Laennec's Cirrhosis (advanced)	77	71 (92.2%)	6	33 (12)	33	0

*Transient positives.

†Proven by biopsy.

2, sciatica 2, abscess and cellulitis 19, undiagnosed disease 11, normals 7, and of the following 1 each:

Epilepsy, beri-beri, hydrocele, erysipelas, botulism, epithelioma, bichloride poisoning, gastritis, Addison's disease, pericarditis, fractured arm, migraine, bromide poisoning, morphine addiction, neurocirculatory asthenia, tenosynovitis, metrorrhagia, bladder stones, kidney stone, chancre, epididymitis, rectovesical fistula, gastro-ecolic fistula, arsenic poisoning, Parkinson's disease, Ayerza's disease, bowel obstruction, salmonella infection, amyloid kidney, purpura, cystic lung, cocaine poisoning, agranulocytosis, Paget's disease, brain tumor, duodenal anomaly, Vincent's angina, amputation neuroma, bronchial stenosis, fractured patella, tuberculosis of the kidney, mucous colitis, malaria, spontaneous pneumothorax, gastro-enteritis, acute enteritis, chronic lymphatic leukemia, pyelonephrosis, infectious mononucleosis, malnutrition, lipid nephrosis.

In the entire series of 1025 cases a positive Takata reaction occurred 118 times. In 87 cases the disease involved was cirrhosis of the liver; in another 6 cases there was severe liver damage; if circulatory changes in the liver may be added to this list another 9 cases are included; 3 more cases had acute glomerular nephritis and 1 had an acute flare up of chronic nephritis; this leaves only 12 positive reactions (5 of which were transient) in 717 cases or a percentage of what might be termed false positives of 1.7. If all cases other than Laennec's cirrhosis are separated there are 31 out of 931 cases or 3.3%.

COMMENT

The results obtained with the mercuric chloride test in this series have been decisively clear cut. As our familiarity with it increased the boundary line between positive and negative became sharper, the percentage smaller of what might be termed "false positives." We were able to do away entirely with the equivocal types of reading advocated by some authors i.e. reading of 1 or 2 tubes as a positive, reading at various time intervals, reading granular precipitates, interpreting color changes. We feel that this makes the test more practically useful.

The statistics on cirrhosis agree in essential parts with those of Jezler, Rohrer, Skouge, Lazzaro, Crane, Schindel and Barth, Ragins, Rappolt, Maneke and Margonis. Hafstrom obtained positives in all 17 of the cases of Laennec's cirrhosis which he described but also found positive tests in numerous other diseases including those from which cirrhosis may be identified by the test. However, Hafstrom counted as positive flocculents—judging from the photographs in his article—various types of precipitation, including the granular type which we regard as irrelevant. He also considers precipitation in 1 tube as a positive reaction. Heath recorded positive tests when precipitation was maximum in 1 or very slight in 3 to 5 tubes, dividing his readings into 5 separate classes. He has, moreover, a large number of cases with "cirrhosis probably present" in whom a negative Takata reaction was found, but in which the correct diagnosis was also questionable; among cases with "established cirrhosis" 28 out of 35 results were positive (80% positive as opposed to 60% in his entire series). Heath's example was followed by Magath whose percentage of positives is likewise small. In our experience the Takata test is more liable to be correct

than the clinician and we feel with Jezler that the clinical diagnosis of cirrhosis is too frequently made.

Although we hesitate in disagreement with Jezler (1934) to proclaim the Takata reaction as a specific test for portal cirrhosis of the liver, our pathological even more than our clinical statistics indicate that a positive reaction in other liver diseases as well as in the population at large is such a rarity that from a practical standpoint it may be regarded as a specific test. In this respect it may be compared to the Wassermann test in syphilis or to the elevation of the blood urea in chronic glomerular nephritis. Neither are specific for their respective diseases and either may occur in other conditions but the presence of either is regarded as information of considerable importance. Thus, while only 1 out of 37 cases of early and advanced cirrhosis proven by autopsy (including 2 cases of yellow atrophy plus cirrhosis) was negative, only 3 out of 43 autopsied cases of other diseases of the liver were positive. One of these was portal thrombosis with multiple liver abscesses, the second clinically acute yellow atrophy and pathologically toxic necrosis of the liver, the third metastatic carcinoma. The amount of liver damage in these 43 cases as well as in 63 other cases not regarded as primarily involving the liver was often extremely marked (of 105 livers, "advanced" in 18, "moderate" in 40). In 7 of the carcinomatous livers the tissue had been very largely replaced by cancer cells; in the 2 cases of acute yellow atrophy with a negative reaction there was extensive toxic necrosis with very little actual liver tissue remaining, this was also true in 2 cases of severe amyloidosis. On the other hand, among the 37 cases of cirrhosis there were 4 instances in which microscopically there was very slight evidence of disease except for the fibrosis (one of the least involved was the case with the negative reaction).

The consistent occurrence of a negative reaction in all of 3 cases of cholangitis with ensuing cirrhosis diagnosed both clinically and pathologically is very interesting. These had changes microscopically as marked as cases of Laennec's cirrhosis with positive reactions. One may raise the question of the similar etiology of late cirrhoses which react negatively.

The occurrence of flocculation in all of 3 cases of acute glomerular nephritis is worthy of comment. Jezler's article affirming the high incidence of the Takata reaction in this condition was unfortunately not read until this series was well under way. The only case of chronic nephritis which had an acute exacerbation after we became aware of the likelihood of a positive reaction during a flare-up did have a positive Takata test although it had been previously negative. The activity of the other 24 cases of chronic nephritis at the time blood was taken for the test cannot be judged.

Clinical Value: Regardless of the fact that the Takata reaction is positive in so great a percentage of cases of cirrhosis of the liver as to be regarded as almost though not entirely specific, one may question its use in the individual instance. There have been certain types of cases in which the Takata reaction has been specifically helpful in differential diagnosis and has given the correct answer when the clinical diagnosis was in doubt or was wrong. In considerable part the confirmation was in the autopsy or in the operating room. These include 7 cases with marked jaundice in which a differentiation was made from carcinoma,

of acute hepatitis; 9 there was a question of Bart's syndrome. In acute the diagnosis of was made on the basis of 12 cases the diagnosis of that of acute hepatitis before the Takata reaction. Four of 4 cases by a positive Takata reaction in 10 other cases which this disease could occurrence of a negative.

There were 7 cases of as developing cirrhosis in reaction were made over. These were patients in which originally negative and reaction was clinically slight amount of protein, increasingly great. One 215 35, M. M., a 34: noted for peripheral Nijmegen, ascites, or 1 m. Liver palpable. F. Takata reaction 0000000 621 35, readmitted 18 cm. below right c. Takata index 57. Takata 726 35, improving. I Abdomen smaller. Ict.

12 31 35, admitted f. anemia. Icteric index 4 2 3 36, improving. Ta 1 3 37, readmitted for ascites, hard liver 14. Icteric index 31, Takata

This patient clinically ing hepatitis with development paralleled the precipitation occurring in disease progressed. It reaction process was Takata reaction was positive we have, however, true—extensive liver fibrosis also. T Takata reaction was positive precipitation; 2 of reaction. If blood were when they were noted among the negative account for the

MECHANISM OF

Many theories have been advanced which mercuric chloride and flocculation of proteins which are in pathologic solution occurs in albumin-globulin reaction of the globulin. The method, for

stone or acute hepatitis; 9 cases with ascites in which there was a question of carcinomatous metastases or of Banti's syndrome. In 11 cases with or without ascites the diagnosis of cirrhosis instead of carcinoma was made on the basis of a positive Takata reaction. In 2 cases the diagnosis of cirrhosis was preferred to that of acute hepatitis because of a very strong positive Takata reaction. Early cirrhosis of the liver was found in 4 cases by checking back after the occurrence of a positive Takata reaction done as a routine test. In 10 other cases which were at first considered cirrhosis this disease could be ruled out because of the occurrence of a negative Takata reaction.

There were 7 cases of what we choose to designate as developing cirrhosis in which serial studies of the reaction were made over a period of months or years. These were patients in whom the Takata reaction was originally negative and in whom the evidence of cirrhosis was clinically slight. As the disease progressed the amount of precipitation which occurred became increasingly great. One example of this may be given:

2/15/35, M. M., a 34 year old married woman admitted for peripheral neuritis and chronic alcoholism. No jaundice, ascites, or evidence of collateral circulation. Liver palpable. Few small spider hemangiomas. Takata reaction 00000000.

6/21/35, readmitted for pellagra and acute hepatitis following prolonged period of drinking. Liver tender, 18 cm. below right costal margin. Ascites present. Icterus index 57. Takata reaction 00012000.

7/26/35, improving. Liver smaller and less tender. Abdomen smaller. Icterus index 22.9. Takata reaction 00002000.

12/31/35, admitted for hematemesis. Macrocytic anemia. Icteric index 41. Takata reaction 00023321.

2/8/36, improving. Takata reaction 00012300.

1/8/37, readmitted for hematemesis. Marked anemia, ascites, hard liver 14 cm. below right costal margin. Icteric index 31, Takata reaction 00033321.

This patient clinically was a case of severe recurring hepatitis with developing cirrhosis. The Takata reaction paralleled the clinical course of the disease, precipitation occurring in more and more tubes as the disease progressed. It may be argued that the cirrhotic process was already far advanced before the Takata reaction was positive. The autopsy material which we have, however, favors the view that this is not true—extensive liver degeneration may be present but not fibrosis also. There were 4 cirrhotics who had a positive Takata reaction who later showed marked improvement accompanied by a decreasing amount of precipitation; 2 of these developed a totally negative reaction. If blood were taken from such patients only when they were entirely quiescent they would be classed among the negative reactors—undoubtedly this does account for the majority of such in this series.

MECHANISM OF THE TAKATA REACTION

Many theories have been advanced to explain the flocculation which occurs. It is generally believed that mercuric chloride and sodium carbonate form a colloidal solution of mercuric oxide in the presence of proteins which are considered to act as protective colloids; in pathological states precipitation of the colloidal solution occurs: Takata himself thought that the albumin-globulin ratio became altered by increase of the globulin fraction (1925). Jezler (4) using the Kjeldahl method, found the globulin fraction con-

stantly over 55% of the total protein in cases with positive mercuric chloride reactions while it averaged around 37% in cases with negative reactions.

Lazzaro (14), Hugonot and Sohler (28), Carrière, Martin and Dufossé (29), Ragins (19), Vigada and Montanari (30), believed that the reaction was dependent on the lowering of the albumin-globulin ratio of the serum. Van Ginkel (7), Rappolt (20), Kirk (23), Gros (31), Hohn (32) and Ucko (33) consider the increase in the serum globulin as the important factor.

On the other hand Skouge (13) and Schindel and Barth (16) found no constancy in the correlation between the occurrence of a positive Takata reaction and either increase in the globulin fraction or lowering of the albumin-globulin ratio. Allesandro (34) working with phosphorus poisoned rabbits agreed with the latter views. Schreuder (35) believed that a positive reaction occurred with either increase of the globulin or decrease of the albumin content.

Medvei and Paschkis (36) found that the addition of heparin to Takata positive sera changed the reaction from positive to negative, although the addition of heparin had been shown by A. Fischer to convert serum albumin into serum globulin.

Schindel (37) added various lower fatty acids to sera with negative Takata reaction to produce flocculation, believed that ketonuria might play a role in the production of the reaction. Gros (31) found no change in the reaction before and after extraction of the fatty acids from the serum. Kallos-Deffner (38) obtained positive reactions in the sera of rabbits with ketonuria produced by starvation or existence in a rarified atmosphere; with restoration of normal conditions the Takata reaction became negative. Allesandro (34) found that a positive Takata reaction in his experimental rabbits was constantly accompanied by a ketonuria. Recht (39) found a positive Takata reaction in children with acidosis and dehydration. In our series were at least 2 cases in which such a mechanism is conceivable. One was a diabetic coma with marked ketosis; the Takata reaction was 00001221; 2 days later the patient was clinically improved, had no ketosis, a Takata reaction of 00000000; several checks showed that this remained negative. A similar result was true in a case of leprosy which had been given artificial hyperpyrexia; at the height of the fever the Takata reaction was 00002333; twice afterwards it was 00000000. (It may be noted that in both these cases precipitation begins in a dilution higher than it does in the cases of cirrhosis).

Oefelein (40) found the ammonia content of the blood high in cases with positive Takata reactions.

Staub and Jezler (41) conclude that the Takata reaction represents not a function but a dysfunction of the liver, dependent on the colloidal composition of the serum.

Jurgens (42) found the Takata reaction negative after removal of the liver in geese, positive after tying the portal vein; in dogs it was positive after the production of an Eck fistula, negative after reversed Eck fistula. He concludes that the test is dependent on the products of metabolism of the damaged liver cells.

Crane (8) suggests as possible causes for a positive Takata reaction:

1. Release of liver proteins into the circulation (i.e. in cases of yellow atrophy).

2. Inability of the liver to alter proteins contained in the blood.

3. Failure of some blood to pass through the liver, going instead (by way of collateral venous anastomoses) directly into the general circulation.

It is extremely difficult to explain the occurrence of the positive Takata reaction by any one hypothesis. Increase in the globulin fraction of the serum, both relatively and absolutely, does occur in the majority of the cases but there are many cases in which it does not. Conversely, there are many cases with changes in the globulin without positive Takata reaction. The presence of liver damage as such appears to play very little role. If the release of liver proteins into the circulation were important acute yellow atrophy should give uniformly strongly positive reactions, but does not. If the reaction were caused by the failure of blood to pass through the liver portal thrombosis should give uniformly positive reactions, but does not. It seems rational at this time to be content with Staub and Jezler that the Takata reaction represents a dysfunction of the liver. It probably is dependent on the colloidal composition of the serum. It probably represents some retention substance which under the usual conditions of its occurrence requires some time to be formed in sufficient quantity to result in a positive reaction (comparable, again, to an elevated blood urea in chronic glomerular nephritis). It is possible that this is a toxic product.

SUMMARY

The mercuric chloride flocculation test of Takata was performed on 1025 cases. A positive reaction occurred 118 times or 11.5%. In 94 cases of cirrhosis of the liver there were 87 positive reactions, a percentage of 92.5.

The percentage of positives in all conditions was 3.3% (of 931 cases), a total of 31 cases. Included in this number were 6 out of 81 cases of severe liver involvement, or 7.4%, 10 out of 122 cases of cardiac decompensation or 7.4% and 4 out of 4 cases of acute nephritis.

CONCLUSIONS

1. The Takata reaction is an excellent test in the diagnosis of Laennec's cirrhosis of the liver.
2. It is of particular value in differentiating cirrhosis from carcinoma with metastases in the liver, in cases with jaundice or with ascites.
3. Liver damage, as such, in the absence of Laennec's cirrhosis, yields a low percentage of positive reactions.
4. Failure of precipitation in a questionable case is a fairly certain indication that cirrhosis is not present.
5. In a few instances the diagnosis of cirrhosis can be made before clinical signs appear.
6. In developing cirrhosis the reaction may be negative at first, to become positive as the disease progresses.

Chronic Ulcerative Colitis: An Analysis of 88 Cases*

By

ISIDORE A. FEDER, M.D.
BROOKLYN, NEW YORK

FROM 1922 until the end of 1930 there were admitted to the Beth-El Hospital 23 cases of chronic ulcerative colitis. Since 1930 we have treated 65 patients for this illness. This marked increase in incidence of chronic ulcerative colitis on our hospital service during the present decade has prompted us to review the recent literature relative to this disease and to present an analysis of the 88 cases which have been admitted to our institution.

DEFINITION

Chronic ulcerative colitis is an inflammatory condition of the colon, usually extending upwards from the anus, involving the colon either partially or along its entire course from the anus to the cecum. It is a specific entity, not uncommon in incidence, running a prolonged and intermittent course, with serious complications and frequently fatal in its outcome.

ETIOLOGY

The signs and symptoms in the patient who presents himself for examination and treatment unquestionably point to the infectious nature of the disease. Much difference of opinion has existed relative to the etiology of this condition. Is infection the primary etiological factor? Is infection secondarily imposed upon a colon which, for other reasons, has lost its normal resistance to bacteria which ordinarily inhabit it? Is the infection similar or akin to other well known forms of colon inflammation? The confusion resulting from the answers to these questions has complicated the approach to the disease and made more difficult the method of treating it.

Evans (1) suggests that the terms pylorospasm, gastritis or duodenitis, and peptic ulcer represent steps of one disease process in the stomach or duodenum and that the disease is manifest in the colon through spastic colitis, mucous colitis, catarrhal and ulcerative colitis. Drucek (2), Kuttner (3), and many other recent writers hold that ulcerative colitis indicates a late stage of the spastic colon. On the other hand Barger (4) states that the number of cases in which chronic ulcerative colitis follows the irritable colon is very small, and would not justify the belief that the latter is a forerunner of chronic ulcerative colitis.

Because of the appearance of symptoms of avitaminosis in some patients certain authors have felt that vitamin deficiency in some form may be the initial cause for the onset of the disease. This concept does not appear to be borne out clinically. All of our cases occurred in individuals whose dietetic habits did not deviate to any marked degree from the normal. Three of our cases showed evidence of vitamin deficiency. Two patients presented the skin manifestations of

pellagra and in one the beriberi type of heart was discovered at autopsy. In view of the fact that these symptoms appeared either in the late or terminal stages of the disease, it is assumed that the vitamin deficiency is rather a result of improper absorption and utilization in, than a cause of, chronic ulcerative colitis. Dukes (5) and Barger (4), who have carried out studies of the life habits of many series of patients found no evidence of vitamin or other deficiency playing a part in the causation of the disease.

Some authors have ascribed a disturbed metabolism as an etiological factor. Portis (6) suggests a thyrotoxic cause for the disease. Basal metabolic readings in six of our patients showed the rates to be normal in four, slightly above normal in one and slightly below normal in another.

Recently the psychogenic origin of the disease has received considerable attention. Sullivan (7, 8) found psychological difficulties in 18 of 25 consecutive cases of ulcerative colitis, in 15 of which the emotional disturbances appeared to be of definite etiological significance. He found a well marked time relationship between emotional crises and the onset of the disease or its recurrences. Murray's (9, 10) reports are confirmatory of this idea. Reehad (30) and Sullivan (8) found that psychotherapy was a successful method of treatment in chronic ulcerative colitis. 72% of our cases occurred in young adults between the ages of 16 and 40, in many of whom the problems of sex, marriage or finances might have been responsible for the creation of a psychological conflict. Five of our patients gave histories of having had "nervous breakdowns" previous to the onset of the colitis. We have called attention to the marked increase in the number of cases at our hospital since 1930. It is of interest to note that this is coincident with the period of economic depression which set in at that time. Economic and financial worries may possibly have been the exciting factors in a number of these patients.

Turner (11), Hurst (5), Hern (12) and Penner (13) feel that the disease is a form of bacillary dysentery. Winkelstein (14) reports that 20% of his cases are due to this condition. These authors base their reasoning on the response of many patients to specific treatment with anti-dysenteric serum. However, as Dukes (5) and Barger (4) point out, the negative bacteriological and epidemiological evidence, the absence of agglutination and the uncertain effect of antidyenteric serum seem to discount this point of view.

Fradkin (15), Winkelstein (14) and others feel that the ameba may be a cause of chronic ulcerative colitis. It is undoubtedly true that a number of cases of amebic colitis are mistakenly diagnosed as chronic ulcerative colitis. But where the diagnosis is not supported by laboratory evidence or by effects of anti-

Fig. 1

amebic therapy, one can hardly see any reason for attributing to this organism the responsibility for this disease.

Bassler (16) found that in young subjects *Clostridium Welchii*, enterococcus and green and non hemolytic streptococcus is the infective trilogy and that in adults the hemolytic streptococcus is most often met with.

Bargen (4) and other workers have established a diplostreptococcus of characteristic morphologic and biologic properties as the main causative organism of chronic ulcerative colitis. The diplococci, when isolated according to the method of Bargen, are fused in pairs, almost merging into chains of four cocci, are lancet shaped and gram positive. The diplococcus has been isolated in pure culture from the rectal lesions of 80% of his cases at the Mayo Clinic. The lesions of ulcerative colitis have been reproduced in rabbits and dogs by the intravenous injections of many strains of this organism. It has been recovered from the blood in acute fulminating cases. It has been found in foci of infection such as peridental or peritonsillar abscesses and cultures of these reproduced the disease in animals. Cock (17) produced periapical dental infections in dogs and two to 16 months later the proctoscopic picture of chronic ulcerative colitis was demonstrated. People in normal health have been found to be carriers of this organism. It has been isolated in the stools of patients with vague abdominal complaints who later developed the typical picture of chronic ulcerative colitis.

Many authors have cast doubt upon the contention of Bargen that the diplostreptococcus is the chief offending organism. Portis (6) states that no positive blood cultures are found. However, one can rarely obtain positive blood cultures in most diseases which have been initiated by infection from a distant focus. Bassler (17) recovered the diplococcus in 44% of his cases of ulcerative colitis and in 37% of 500 cases of

non-ulcerative colitis, yet feels that it is not the etiological factor in the disease. Rafsky (18) states that the diplococcus is a strain of the enterococci group. Bargen has definitely shown significant differences between the two; namely that on mannite agar the appearance of the colony of the diplococcus is fine and translucent; the enterococcus grows as a large, white opalescent colony on this medium. The diplococcus does not grow on plain agar; it does not grow on gelatin; it usually does not coagulate milk. The enterococcus does all of these readily. Dukes (5) feels that the diplococcus and other types of fecal streptococci are secondary invaders and that the bloody diarrhea produced by intravenous injection in rabbits does not follow the course of human chronic ulcerative colitis and that the same result is produced by other bacteria.

In our series of cases the diplostreptococcus was isolated from 16 patients or 18% of the total. Rarely did we make repeated examinations after failure to isolate the organism on the first attempt. It is probable that, if the technical details and suggestions of Bargen were carefully followed out, many more cases would reveal the diplococcus as the offending organism. The enterococcus was isolated in six cases or 7% of the total. A green streptococcus was isolated in two patients and a hemolytic staphylococcus in one. No specific organism was isolated in 63 patients or 72% of the entire group.

The exacerbations of this disease following upper respiratory infections and the removal of foci of infection lend support to the belief that the disease is infectious in nature. Seven of our patients had acute exacerbations after upper respiratory infections and one after a pleurisy. Tonsillectomy caused an exacerbation in one. The extraction of a number of teeth led to an acute fulminating exacerbation in one case with death from sepsis.

Fig. 2

The following report substantiates in every detail Bergen's claims as to the etiology of chronic ulcerative colitis and clearly illustrates the role of a focus of infection in the onset and recurrence of symptoms.

Case No. 57081, J. S., male, age 17. Admitted January 9, 1933, with a history that two months prior to admission, following a cold, the patient developed a diarrhea and shortly thereafter noticed blood in the stools. After treatment with medicines his condition improved. He then had another upper respiratory infection which brought with it a more severe recurrence of symptoms and hospitalization was advised. On admission, patient was having numerous loose stools containing blood and pus and on many occasions passed only clots of blood. There were severe abdominal cramps and marked weakness. Temperature was 103. White blood cells numbered 20,200 with 80% polymorphonuclear cells. Hemoglobin was 55% and red cell count 2,575,000. Barium enema showed a spastic

admission tonsillectomy was performed. This was followed the next day by an increase in the number of stools which contained blood. Examination of the stool at this time showed numerous diplococci. Culture of the tonsils disclosed a pure culture of diplostreptococci, the same organisms which were noted in the stool. Another autogenous vaccine was prepared and administered for six weeks. Patient was discharged as cured on January 3, 1934. There has been no recurrence of symptoms to date.

Five patients had acute recurrences during pregnancy and two had therapeutic abortions performed for this reason. Two patients had recurrences after appendectomy and three after hemorrhoidectomy.

Patients of all ages and of both sexes are affected by this disease. The youngest in our series was seven years of age, the oldest 70. 62% of our cases occurred in females (Table 1).

In only one instance were two members of one

Fig. 3

colon which filled very rapidly. Sigmoidoscopy disclosed numerous ulcerations in the rectum and sigmoid, exuding a bloody and mucopurulent discharge. Smears taken from the stool and stained revealed a preponderance of diplococci singly and in chains (Fig. 1). Culture of the stool showed almost pure culture of the same organism. Repeated transfusions were given to tide the patient over the acute phase of his illness. A vaccine prepared from the organisms isolated in the stools was administered. Five weeks after administration of the vaccine direct smears from the stool showed clumps of agglutinated diplostreptococci (Fig. 2). (This was probably caused by the presence of agglutinins in the serum of the blood which had exuded through the colonic mucosa and agglutinated the organisms). The patient was discharged markedly improved on February 16, 1933. Vaccine treatment was continued at home for three months. At the end of this time no diplococci were found in either the smear (Fig. 3) or culture from the stool. Patient felt well and had three to four bowel movements per day which were occasionally streaked with blood. On November 4, 1933, patient was again ill with an upper respiratory infection. Shortly thereafter there was a recurrence of the severe diarrhea. He was readmitted to the hospital November 18, 1933, for tonsillectomy. Stool examination at this time failed to show the diplococcus. The number of stools lessened under medical treatment and a few weeks after

family affected; a young girl who developed symptoms shortly after the death of her sister from chronic ulcerative colitis.

SIGMOIDOSCOPY (GROSS PATHOLOGY)

In the greatest number of cases the pathologic process is initiated within the lower limits of the rectum and extends upward toward the sigmoid and descending colon. The initial stage is characterized by an acute inflammation of the mucous membrane of the colon. It appears diffusely hyperemic. This is shortly followed by an edema of the mucosa which becomes boggy and readily bleeds when slightly traumatized by the sigmoidoscope. Minute abscesses appear beneath the surface of the mucosa which slough away and leave small, pin point, bleeding ulcers. At this stage the mucous membrane appears diffusely granular and bleeding. The union of these minute ulcers may produce ulcers of larger dimensions and secondarily imposed infection will alter their appearance. During the stage of remission the pin point ulcers may heal and leave small scars. In the late stages of chronic ulcerative colitis, when great difficulty may be encountered in differentiating this disease from other forms of

colitis with ulcerations, the presence of these small, pit-like scars is of utmost importance in making the diagnosis. As a result of the diffuse scarification with formation of fibrous tissue the wall of the bowel becomes contracted and the lumen narrowed from slight to extreme degrees. Strictures may develop in cases where the pathologic process has been more severe and fibrosis more marked. Purulent exudate, dammed up by these strictures, may produce large abscesses.

seen. Only ragged strips and bridges of mucosa course irregularly across the inner aspect. Between these lie exposed submucosa, muscularis or serosa.

MICROSCOPIC EXAMINATION

The mucosa is for the most part absent. In one place most of the thickness of the submucosa is also gone. The cells along the surface of the mucosa show degeneration. In the mucosa there is an infiltration

TABLE I
Age incidence

Female	0	3	12	21	6	6	5	2	55

When the ulcers heal, ragged polypoidal tags of mucous membrane remain. (These must not be confused with true adenomatous proliferations). When these infected ulcers extend into the deeper layers of the colon the danger of perforation is imminent.

The following chronologic reports exemplify the sequence of protoscopic findings in one of our cases:

Case No. 82697, F. L., female, age 16. Admitted March 4, 1937, with history of diarrhea of five weeks duration, the stools during the latter two weeks admixed with blood and pus. Sigmoidoscopy March 11th; markedly congested mucosa. Bleeds readily. Many small, whitish areas under the mucous membrane (Abscesses). Many small ulcerations. May 26th: Acutely congested mucosa. Many small and larger ulcerations. Many small, pit-like scars noted throughout the mucosa. July 7th: Mucosa much paler but thickened and scarred. Few polyps noted.

The following case exemplifies the ascending nature of chronic ulcerative colitis and the danger of pronouncing a patient cured without thorough and long follow up:

Case No. 32941, E. K., female, age 20. Admitted March 9, 1929, with a history of three days of bloody diarrhea. March 11th—proctoscopy reveals an ulcerative proctitis extending only two inches above the anus. Patient was apparently cured with rectal instillations of bismuth subnitrate in olive oil and discharged April 29th. Patient was readmitted on November 18, 1929. There was a recurrence of bloody diarrhea after an upper respiratory infection. Sigmoidoscopy revealed pin point abscesses with small and button sized ulcers throughout sigmoid and rectum, penetrating through the mucosa and submucosa.

The following gross and microscopic pathologic description indicates the marked destructive process in a case of longer standing:

Case No. 81796, M. J., female, age 29. Admitted January 13, 1937, with a history of diarrhea of four years duration. Patient died February 1, 1937, of a generalized peritonitis due to perforation of the colon. At about the hepatic flexure, small mucosal ulcerations are first noted. These grow very extensive along the transverse colon partly encircling the bowel. They possess ragged, undermined edges with a base made up of submucosa, muscularis, and along the attachment of the lesser omentum only peritoneum. The peritoneum presents longitudinal rents encircling the bowel, affording communication between the colon and peritoneal cavity. The descending colon, sigmoid and rectum present a more advanced degree of the lesions. The bowel is thickened to about 0.5 cm. No normal mucosa is

of lymphocytes and plasma cells and some edema. A few polymorphonuclear cells are also noted. Where the mucosa is absent the surface is covered with cellular debris and polymorphonuclear cells. There is an increase in fibrous tissue and some edema of the submucosa. It is infiltrated with lymphocytes, plasma cells, histiocytes and polymorphonuclear cells. A lymph node in the serosa shows a widening of its sinuses and these hold histiocytes.

SYMPTOMS AND DIAGNOSIS

The disease may start insidiously. The patient may complain of vague abdominal pains, increased frequency of stools with an excessive amount of mucous. The stools are loose in consistency. After a variable period of time the patient will notice blood admixed with the stool and later the presence of pus. There may be slight or even no elevation of temperature. The patient has frequent calls to stool and may pass only hemorrhagic or purulent rectal discharge without fecal matter. In the fulminating case there is a rather abrupt onset with high and occasionally septic type of temperature. The patient appears acutely ill. There are numerous loose purulent and bloody stools. The patient shows all evidence of a profound toxemia.

Later the patient presents a picture of inanition and dehydration. There is marked loss of weight, pallor and anxiety. 46% of our cases had a marked secondary anemia. 8% had achylia gastrica. The leucocyte count and sedimentation rate were increased especially in cases with hyperpyrexia.

The diagnosis rests upon the history and sigmoidoscopic findings as aforementioned, the physical examination and the appearance of the colon on the X-ray film after examination with the barium enema.

Physical examination of the abdomen will disclose a firm, tube-like descending colon and sigmoid which may be tender to palpation. Digital examination of the rectum discloses a spastic sphincter. The lumen is narrowed. The mucosa is granular and, if ulcerations are deep, they may be noted by the examining finger.

The appearance of the colon with the barium enema depends upon the stage of the disease, the extent of the ulceration and the presence of sequellae. The colon fills rapidly. Where the ulcerations are small and superficial the outline of the colon is smooth and shows a notable lack of haustration. Where the ulcerations are deeper the outlines of the colon are feathery, a

characteristic picture of the disease. Where ulceration is deep, and irregular fibrosis has occurred, the outline is rough and irregular. Because of the fibrosis of its wall the colon becomes narrowed and shortened. Examination by the contrast enema, where air is injected into the colon following the expulsion of the barium, will more easily outline ulcers and polyps.

COMPLICATIONS

Stricture of the bowel is commonly seen. It is the result of the fibrosis which takes place during the stage of healing. One is struck by this condition when one finds marked difficulty in passing the sigmoidoscope because of the narrowed lumen. It is wiser to stop the examination than to attempt to forcibly push one's way past the stricture. Perforation of the bowel resulted from this procedure in one of our early cases. 13 of our cases were complicated by stricture.

Polyposis (improperly termed because the polypoidal tags of mucous membrane which remain after healing are not true polyps) is frequently noticed on proctoscopic examination. If present higher up in the colon they are well visualized on the X-ray by means of the contrast enema. 11 of our cases were complicated by polyposis. When large these false polyps may aggravate the symptomatology.

Perforation of the colon with a resulting peritonitis occurs when ulceration has penetrated the serosa of the colon. This was observed in three and the cause of death in two of our cases. Penetration of ulcers in the perirectal and perianal regions may form perirectal abscesses which then may rupture through the skin, vagina or bladder and produce fistulae. Nine of our cases showed these complications.

Vitamin B deficiency was found in a case which revealed a beriberi type of heart at autopsy. There was myocardial atrophy, edema and vacuolation of the heart muscle. Two cases of vitamin G deficiency were noted—a roughness and dark discoloration of the backs of the hands and forearms as is seen in pellagra.

There was an inversion of the serum albumin and globulin ratio in two cases. There was hypoproteinemia in three cases, two of which revealed evidence of a nutritional edema.

Arthritis complicated two of our cases. Hepato and splenomegaly was found in one case.

Bargen (4) and Hurst (19) in addition note such complications as renal insufficiency, ocular lesions, peripheral neuritis, progressive arterial occlusion, multiple abscess of the liver, tetany and carcinoma. Carcinoma is not as common a complication as is found in true polyposis or multiple adenomata of the intestine. This is probably due to the fact that the polypoidal masses are not true adenomatous proliferations.

PROGNOSIS

Primary recovery within a few weeks has been reported. We have never seen it. Exacerbations and remissions are common. One must not fall into the error of pronouncing a case cured merely on freedom of symptoms or even with apparently healed lesions on examination of the colon, unless the patient has been followed up for a reasonably long period of time.

Hurst (19) feels the mortality should not exceed 5 to 10% if the patients receive adequate treatment for sufficient periods. He states that the large majority should recover eventually so completely that they are able to lead a life of normal activity. Bargen (20)

states that X-rays show a tendency of the bowel to return to normal in 40% of the cases. Crohn and Rosenak (21) in a series of 75 cases report 33 cured, 23 improved, 8 unimproved and 11 died. Kiefer (22) divides his cases into the non toxic—non sclerotic of which he reports 78% cured, the non toxic—sclerotic of which 50% recovered and the toxic where 38% showed satisfactory improvement and where the mortality was 25%.

In our series of cases only two or 2.3% have been pronounced cured, one after a period of four years and another after two years. 21 cases or 23.8% were unimproved at the time of discharge. 10 patients or 11.4% died; two from perforation with peritonitis, three from severe toxemia, one from sepsis resulting after extraction of teeth, one from broncho pneumonia, one after appendectomy, one after appendicostomy and one after ileostomy. 55 cases or 62.5% were discharged as improved, many of these to return later with exacerbations. The best that we could say for the latter group of cases was that the patients were improved because the degree of involvement of the colon on sigmoidoscopic examination was less on discharge than on admission.

TREATMENT

Many varieties of treatment have been used in the attempt to cure chronic ulcerative colitis. Hare (23) feels that no treatment has been found that acts as a specific cure in an attack of this disease or that will prevent a relapse.

Rest in bed is essential when the patient is acutely ill, i.e. when there is hyperpyrexia, leucocytosis, increased sedimentation rate and very frequent bowel movements. Bargen (4) feels that when the acute infection has subsided the patient should be given some form of occupational therapy to distract his attention from the need of remaining near a toilet room.

Where the psychiatric background has been studied and psychological difficulties or emotional disturbances appear to be of etiological significance, Murray (9, 10), Rechad (30) and Sullivan (8) have found psychotherapy to be of distinct value.

DIET

Hurst (24), Bargen (4), Kiefer (22) and others specify various diets used in treatment. Suffice it to say that the ideal menu consists of a well balanced, high caloric, high vitamin diet, with foods digested mostly in the stomach and small intestine, and leaving as little residue as possible for the colon. Because of the rapid peristalsis there is little absorption in the colon and undigested food in the bowel is a source of irritation. Where hypoproteinemia is present, the protein content of the food should be increased. Synthetic preparations of all the vitamins are used orally, and parenterally when the patient is unable to retain them by mouth.

Many drugs are useful in alleviating the distressing symptoms of the disease but none has as yet been proven to be specific in its cure.

Some form of opium or codeine with belladonna will slow peristalsis and relieve abdominal cramps. Bismuth and kaolin will thicken the contents of the colon and reduce the number of bowel movements. Charcoal will absorb gases and relieve colic. Dilute hydrochloric acid should be given where there is achlorhydria. Iron is prescribed for the secondary anemia.

Stimson (25) advocates the use of sodium reioleate by mouth in order to detoxify the upper bowel, and as an irrigation in 1% solution in order to aid the elimination of toxic and infective products from the colon. Its use has not been attended with any improvement in our cases. Castor oil has been recommended for the same reason. Its use is to be condemned. Multiple perforations of the colon with a fatal peritonitis resulted in one of our patients.

Andresen and D'Albora (26), in addition to general methods of treatment, also use mercurochrome intravenously. They begin with a dose of 15 cc. of 0.5% solution and increase the dose at four day intervals sufficient to cause a febrile reaction of 101.5 to 102.5. They cite a number of cures.

The widespread use of sulfanilamide in infection has probably prompted many investigators to use this drug in the hope that it might be the long sought for specific. We have tried it in three cases, using 30 to 40 grains daily in divided doses for a period of two weeks and then repeating the course of treatment after a period of two weeks of rest. We have found no apparent benefit from its use. In fact it may have been responsible for an increase in the diarrhea of one of our cases and for an elevation of temperature in all three where such temperature was not present before its use.

Anti-amebic drugs such as emetine, etc., should be used where there is a question, no matter how slight, of the possibility of the condition being due to amebic colitis.

LOCAL TREATMENT TO THE COLON

Solutions of saline, potassium permanganate, acriflavine, mercurochrome, etc., have been used as colonic irrigations. The rationale of this form of treatment has never been proven. At their best, irrigations will merely cleanse the surface for only a few moments. The infection situated deeper in the coats of the colon cannot be reached by the irrigating solution. Kiefer (22), Hare (23) and Bergen (4) feel that the irritation caused by this form of treatment offsets whatever possible good can be obtained from its use.

Retention enemata have been found to be of value. Hurst (24) recommends the use of tannic acid solution, $\frac{1}{2}$ to 2 grains to the ounce, 1 to 1½ pints to be retained for ½ hour. Kiefer (22) uses a starch and opium retention enema to relieve tenesmus. Crohn and Rosenak (21) use neutral acriflavine (1:4000 parts of normal saline). Fradkin (27) used a mixture consisting of 20% kaolin, 10% mineral oil and 70% of a gel of aluminum hydroxide by retention enema in the convalescent patient where the stools were streaked with blood. As an adjunct to specific therapy this method aided in reducing the number of stools and healing the mucosa. Eyerly and Breuhaus (28) use a retention enema consisting of a three to five ounce mixture of kaolin and aluminum hydroxide in from three to five ounces of warm distilled water. Usually one but occasionally two retention enemata are given daily. The objection to the use of these enemata is the inability of the patients to retain them without marked discomfort for more than a few moments.

Soper (32) uses daily insufflations of calomel and bismuth subcarbonate and reports a number of cures

in his early cases of chronic ulcerative colitis. We found no improvement in three of our cases from this form of therapy.

SUPPORTIVE MEASURES

The intravenous use of saline and glucose is indicated in cases of dehydration and starvation accompanying marked diarrhea. In hypoproteinemia with its resultant nutritional edema we have found the use of acacia intravenously to be of value.

TRANSFUSIONS

Bergen (4) uses repeated transfusions of about 200 cc. of blood four to seven days apart to fight the toxemia in cases of severe sepsis and for the anemia and weakness following the loss of blood. Hurst (24) recommends transfusion when the hemoglobin falls below 70%. We have used transfusions in all of our toxic or anemic patients and have found them the best supportive measure to tide the patient over the acute phase of the disease.

SERA AND VACCINES

Hurst (24, 5) and Turner (11) feel that many cases, especially the early ones, respond to specific treatment with anti-dysenteric serum. Crohn and Rosenak (21) use polyvalent antidysenteric serum or typhoid vaccine intravenously. The latter feel that the beneficial results obtained are due to the production of protein shock.

Bergen (4) uses a concentrated serum prepared by immunizing horses against many strains of the diplo-streptococci found in the diseased tissues. This is administered intramuscularly in acute and chronic cases until improvement sets in. Following this a bacterin prepared as an autogenous vaccine from organisms found in rectal ulcers in each case is administered subcutaneously. It is given for several months in increasing doses from 0.1 to 1.5 cc. After a rest of several months it is repeated. Three or four such courses are administered or the vaccine is given until the patient is free of symptoms. After that an occasional course of vaccine is given for several years. Hare (23), Bassler (16), Hurst and Dukes (5) do not believe that Bergen's serum and vaccine are of any value. Alvarez (29) states "It is hard to understand why so many able physicians either stand cold before Bergen's achievements or else are actively hostile to his theories and statements of fact. Many men, when asked if, in trying to confirm Bergen's discovery of the diplococcus, they used his technique, admitted they had not. Few made a thorough going test of his serum and vaccine. Some did not use these measures, others only half heartedly, because they felt any foreign protein would work as well."

In our series of cases the diplococcus was isolated in 16 and the vaccine prepared and given to 11 patients. One was definitely cured and 10 have shown marked improvement. Typhoid vaccine was used intravenously in three cases, two of which showed no improvement and one slight improvement. Autogenous vaccines were prepared from the stools of 11 patients where no specific organism was isolated; four were improved, seven unimproved.

Bacteriophage prepared from the organisms found in the stool has been recommended by some authorities. Both stock and autogenous preparations have been used. They may be given orally, rectally or parenterally. Three of our cases were treated with

bacteriophage, one through rectal instillation and two by means of subcutaneous injections. Two showed no improvement. In one case a stock bacteriophage was used parenterally in conjunction with an autogenous vaccine. This patient has no recurrence after two years.

SURGERY

All evident foci of infection should be eradicated. Most medical authorities feel that surgery of the colon as a cure for chronic ulcerative colitis should be used as a last resort. Hern (12) feels that "internal anastomoses and the like are too stupid in their conception to be worth more than mere mention." Kiefer (22) feels that transverse ileostomy should be done in cases of extreme toxemia. Hurst (24) feels that surgery should be used only in the complications of chronic ulcerative colitis and that colectomy is the procedure of choice. Turner (11) feels that cecostomy should be done to put the colon at rest. Flick (31) reports a case of five years standing cured by total colectomy. Soper (32) reports six of his cases cured by this operation. One of our patients died after appendicostomy, another after ileostomy. One patient showed no improvement after cecostomy.

We advise against elective surgery in the presence of chronic ulcerative colitis. Two of our patients had appendectomies and three had hemorrhoidectomies performed during the course of the disease, all of which were followed by severe exacerbations. One patient died after an appendectomy.

SUMMARY

The recent literature of chronic ulcerative colitis has been reviewed.

An analysis of 88 cases has been presented.

The youngest patient was seven years of age, the oldest 70 years of age. There were 63 cases (72%) which comprised the groups between 16 and 40 years of age. There were 55 females (62%).

No specific organism was isolated in 63 cases (72%). The diplostreptococcus was isolated in 16 cases (18%), the enterococcus in 6 (7%), a green streptococcus in two, and a hemolytic staphylococcus in one.

Five cases gave definite antecedent histories of "nervous breakdowns."

There were 20 instances of recurrences with the following conditions: Seven with upper respiratory infections, one with pleurisy, five with pregnancy, one after tonsillectomy, one after removal of the teeth, two after appendectomy, three after hemorrhoidectomy.

Many complications were encountered, the most frequent being stricture of the bowel, polyposis, perianal abscess and fistula in ano.

In addition to general methods of treatment 11 patients received autogenous vaccines prepared from the stools of whom four were improved and seven unimproved. 11 patients received an autogenous vaccine prepared from the diplostreptococci isolated from the lesions in the colon of whom one was cured and 10 were markedly improved. Three received typhoid vaccine of whom two were unimproved and one improved. Three received bacteriophage of whom two were unimproved and one apparently cured, the latter receiving at the same time an autogenous vaccine prepared from the stool. Three received two courses of sulfanilamide none of whom were improved.

Surgery of the colon was attempted in three patients; cecostomy without improvement; appendicostomy and ileostomy, subsequent to which the patients died.

All patients with toxemia, hemorrhage or secondary anemia received repeated transfusions.

Two patients (2.3%) were cured, 55 (62.5%) were improved, 21 (23.8%) were unimproved and 10 (11.4%) died.

I wish to thank Miss Genia Rabinowitz, bacteriologist at the Beth-El Hospital, for the excellent microphotographs presented in this paper.

The Vitamin B Complex and Functional Chronic Gastro-Intestinal Malfunction: A Study of Two Hundred and Twenty-Seven Cases

By

PASADENA, CALIFORNIA

DISORDERED function of the gastro-intestinal tract appears in animals deprived of vitamins A, B*, C, or D (1, 2). Diarrhea or constipation, spasm or atony may occur. Similarly, it has been recognized for years now that disorders of the gastro-intestinal tract are conspicuous in human nutritional deficiency diseases such as beri-beri and pellagra. In these diseases the factor involved is nearly totally deficient in the diet.

Much less is known and accordingly there is more difference of opinion regarding the incidence and signs of mild, but prolonged vitamin deficiency in humans. Thus the Vitamin Committee of the British Medical Research Council reported in 1932 (3).

"No convincing clinical evidence is available to show that the vitamin B complex determines the normal functioning of the human bowel, and until such is forthcoming it is unnecessary to assume that vitamin B deficiency is concerned in the production of the constipation so commonly met with among Western peoples."

Alvarez (4), though not quite so explicit, is inclined to a similar view. In his opinion disease due to avitaminosis is probably rare in American adults. Accordingly a condition as common as chronic gastro-intestinal malfunction can hardly be the result of vitamin deficiency. Morse (5), is of this opinion also.

Neither the Vitamin Committee nor the above authors have submitted in support of their view explicit descriptions of clinical or experimental investigations. The severity of vitamin deficiency which these authors had in mind is therefore uncertain. From the context it would seem that they meant severe deficiency as in xerophthalmia, beri beri, or scurvy. These diseases are, as these authors maintain, rare now among adults in the United States.

But the point at issue is to what extent are some common chronic ailments such as those of the gastro-intestinal tract the result of suboptimal vitamin intake over a long period. One of the first authors to stress the affirmative view here was McCarrison (2). But it must be admitted that his experimental and clinical observations dealt with severe deficiencies. This, possibly, was one of the reasons for the refusal of the Vitamin Committee to accept his view. Since the work of McCarrison, and in part stimulated by him, a number of reports have appeared in which a definite

connection has been shown between chronic gastro-intestinal malfunction in human beings and subacute vitamin B deficiency. Thus Fletcher (6) and Fletcher and Graham (7) presented X-ray evidence that disturbances of the colon such as loss of tone, decreased or absent haustral markings, and increased length, can be relieved by a high vitamin B, low carbohydrate diet. Marks (8) reported marked relief of constipation, improvement in appetite, strength and vigor in a fairly large number of patients following the daily ingestion of 15 grams of wheat germ daily. A similar experience in a smaller group of cases was reported by Montague (9). The results of an intensive study of two well-controlled cases were reported by Elsom (10). She observed that marked relief from anorexia, epigastric distress, constipation and asthenia were obtained following the administration of large doses of brewers yeast. The improvement was much less with purified single components of the B complex. Vorhaus, Williams and Waterman (11) reported a small group of cases in which constipation was relieved by large doses of crystalline vitamin B₁.

With the exception of those reported by Elsom none of the above patients were cases of obvious vitamin B deficiency. Presumably they had been living on the "usual American diet" which Alvarez and Morse consider supplies adequate amounts of all the vitamins. The results obtained by these investigators with large supplements of vitamin B indicate that there is a pathological insufficiency of vitamin B which is not as severe as frank beri beri or pellagra and that this condition is probably common, if one may judge from the prevalence of chronic constipation.

The study reported here was begun four years ago. Scrutiny of a number of diets selected at random found, similar to Eddy (12) and Marks (8), that the vitamin B intake of most people is little above the anti-beri beri protective level. For instance, few adult diets, even among the well-to-do, contain 400 International units of B₁ daily, which is twice the anti-beri beri level. To this is added, as a rule, a high carbohydrate intake which requires increased amount of B₁ (1, 13). The specific purpose of our investigation was to ascertain whether "functional" gastro-intestinal malfunction may be ascribed to any extent to a chronic partial vitamin B deficiency.

Though unaware of it at the time this study was a re-examination of the question on which the Vitamin Committee of the British Medical Research Council

*By vitamin B we mean, unless stated explicitly otherwise, the whole B complex.

had already given an opinion. It may be stated here that after four years of close observation of over 250 cases our findings disagree with the opinions of the Vitamin Committee, Alvarez and Morse. They support the view first emphasized by McCarrison, and the later corroboratory observations cited above.

The contribution we aimed to make to this controversial question was a closer study over a longer period of a larger number of cases than has yet been reported in this connection. The method of investigation employed was designed to meet the following requirements: 1. The diet, though adequate from a nutritional point of view, must be simple and practical enough to be carried out in the home; though standardized it must contain enough variety to satisfy a large number of cases; and not so rigorous that the

TABLE I

Summary of the effects of different nutritional treatment of 67 cases of chronic gastro-intestinal malfunction

Regime and Type of Case	Number of Cases	Number Improved	Number Not Improved
On regime alone without additional vitamin B supplement	67	18	49
Those not improved on regime alone subsequently given cereal vitamin B supplement	21	13	8

patient will want to abandon it after a short trial. 2. The patients are to be studied in dispensary and private practice. Nevertheless the method of observation should yield approximately objective records.

The main difficulty was to obtain satisfactory objective records. Only cases with "functional" disturbances of gastro-intestinal function were accepted for study. By definition therefore there were no obvious significant signs. There were only symptoms—constipation, intra-abdominal pain, gas, a feeling of fatigue, etc. Radiograms of the gastro-intestinal tract did not yield any concordant instructive information. Some showed a spastic colon, others a dilated colon, in most the shape and emptying time were normal. The uniformity in these cases was in the symptomatology. Accordingly we decided to enlist the cooperation of the patient in observing the changes in his condition, especially as in any case the important information would be obtained from his answers to our questions. The uncertainty of this information was reduced, we feel, by the long period of observation, by our own periodic examination, by the concordance of the changes noted in a large group of cases under widely varying conditions, and by the method we employed (described below) for obtaining these records.

There are four main features in the regime insti-

tuted: (1) the provision of what may be called a balanced diet; except (2) that the carbohydrate content was reduced by the elimination of such "visible" sources as sugar, potatoes, white flour, etc.; (3) the provision in most cases of a high intake of vitamin B in the form of a special cereal described below or of a liquid concentrate; and (4) stopping the use of laxatives, intestinal lubricants, cathartics, and enemata.

The details of the regime and the management are as follows. Every patient was given the following instructions on a mimeographed sheet:

1. No bread, neither whole wheat nor white, no potatoes, neither sweet or plain, no pie, nor candy must be eaten.
2. Drink at least 1 pint of milk daily, 1 glass of orange juice or tomato juice, and 4 glasses of water. Eat at least 1 egg daily, not raw, best boiled for 3 to 5 minutes.
3. Eat a liberal helping daily of green vegetables, such as spinach, carrots, string beans, broccoli, lettuce, asparagus. Do not cook vegetables in a lot of water. Do not throw away the water. Mix it with your food.
4. If you feel that you want to eat more, fill up on milk, meat, and vegetables.
5. Do not take enemata, laxatives, headache medicines, or other remedies except as directed.

Most of the patients received a vitamin B supplement consisting of 100 grams (dry weight) of a special wheat cereal. The technical name of this cereal among millers is "the scalp of the sizings." At present its composition is not quite uniform. It contains on the average 10 to 15 per cent of germ, and the finely ground inner branny layers. The bulk of it consists of protein and starch of the adherent endosperm. This cereal was found to contain from 5 to 10 International Units of vitamin B₁ and about 3 units of the B₂ complex per gram of dry weight*. Our instructions for the use of this cereal are: 1 standard measuring cup of dry cereal cooked with 1 to 2 parts of water in a double boiler for 15 minutes to ½ hour; to be eaten with whole milk, preferably all at breakfast, the remainder may be eaten at luncheon. This is a large quantity of cereal; but most of our patients had no difficulty after about a week in taking this quantity at breakfast. Those for whom it was too much were advised to take some of it as muffins or pancakes.

This cereal fraction is the cheapest, palatable source of the vitamin B complex available at present. It keeps well (for several months in a cool place). It is more palatable for most of our patients than other cooked cereals. It contains a remarkably large amount of the vitamin B complex.

The restriction of carbohydrates in the above regime is based on the fact that normal carbohydrate metabolism is dependent on vitamin B₁ (1, 13). Accordingly the requirement of this vitamin is partly dependent on the extent of the carbohydrate metabolism. If the gastro-intestinal difficulties of our cases were in part at least a consequence of prolonged mild or subacute vitamin B deficiency, it seemed a rational procedure to increase the effectiveness of the vitamin B ingested by restricting the carbohydrate intake. We have estimated that even in our prescribed diet carbohydrate contributes about one-half of the caloric value.

*We are indebted to Mrs. M. K. Dimick of the Vitab Company, Berkeley, for the biological assay of this cereal. The B₂ complex was estimated before it was fractionated into flavine and other components.

TABLE IIA

1 2 10 16 20 19 10 2

Females 62 per cent.

No effort was made to reduce the amount of roughage in the diet. The pureeing of vegetables was not recommended; and there is some bran in the cereal. This bran, it must be noted, is much more finely divided and lighter than the commercial varieties of bran, which are derived from the outer branny coats. Many of our cases had been living on bland diets, with pureed vegetables, etc., following courses of sanatorium treatment for "colitis." These were at first alarmed at the amount of roughage in the diet prescribed. Nevertheless only one of more than 250 cases found the diet irritating.

Each patient was given a mimeographed questionnaire sheet on which he recorded daily his condition under the following headings:

Bowel movements, number and character; abdominal pain, character and location; gas, bloating, belching, passage by the bowel; blood or mucus in the stool; nausea; vomiting; appetite; nervousness; fatigue; headache; cold hands and feet; other disturbances or illnesses; exercise taken; any unusual trip or entertainment; sleep, time of retiring and of rising; have you omitted from the diet any of the prescribed items?

The form of the sheet provided for daily answers

for seven days. The patient presented himself with these records at intervals which varied from one to four weeks. He was then interrogated regarding his condition and his answers; and his own questions answered. He was examined whenever changes in his condition or his complaints seemed to call for it. It should be noted here that the observations on the number and character of the bowel movements may be considered as approximately objective.

We eventually possessed a detailed account of the day to day state of the patient over a long period—in some cases for as long as four years. Our estimate therefore of whether the patient was better or worse in any respect is not based on the patient's statement at any one time, but on a comparison of the records over a long period written each day. The patient had, of course, after a few months forgotten the details of his early records. Hence his later written statement of his condition was relatively independent of his opinions and feelings some months previously.

The cases chosen were from dispensary and private practice. We felt that although a small group of patients confined to hospital afforded an opportunity for better control and intensive study, the conditions are artificial. Any improvement obtained might be maintained only while the patient is living in the special conditions of the investigation. On the other hand any amelioration which had set in while the patient was living in his usual environment carrying his burden of social obligations, not only was likely to be more permanent, but the treatment and the investigation could be carried on for a longer time and with many more cases.

Some of the tentative diagnoses with which the patients were referred to us were: spastic constipation, atonic constipation, chronic gastro-enteritis, colitis, chronic arthritis, hypertrophic arthritis, polyneuritis, epilepsy, malingering, hysteria associated with constipation. In all of the cases accepted for this study the derangements of the gastro-intestinal tract, as far as we could ascertain by clinical, laboratory, and radiological examination, were of the "functional" type. This selection was made, as stated above, to test the hypothesis that a contributory factor in these cases is long standing, partial vitamin B deficiency.

The results obtained summarized in Tables I and II appear to verify this hypothesis. They are not definitive proof because of the difficulty, which the selection of cases entailed, of obtaining thoroughly objective records. On the other hand our records and observations are sufficiently extensive, well checked and concordant, to be taken as indicating that chronic partial vitamin B deficiency (or suboptimal intake) is probably one of the factors "in the production of the constipation so commonly met with among Western peoples," and of other signs and symptoms of chronic gastro-intestinal malfunction in adults.

Before discussing the main body of our results which are summarized in Table II we shall describe first those obtained in a group of 67 cases (not included in Table II) where an effort was made to appraise the relative importance of the management of the case, the character of the diet, and of the vitamin B complex.

These 67 cases were first given the diet alone without the cereal or other vitamin B supplement. Eighteen of these obtained such marked relief on this regime that no other treatment was necessary. In this group,

as in all the others where definite improvement was obtained, it occurred quickly, often within 2 weeks, and in no case later than 6 weeks. The constipation corrected itself first, later the dyspepsia and abdominal discomfort or pain, then anorexia disappeared. Gradually a marked improvement in the sense of general well-being, diminished fatigue or asthenia were noted. Gas was the most persistent symptom and the one from which least relief was obtained and least often.

Twenty-one of those who had shown no improvement after 2 months on the diet alone now received the cereal supplement. Thirteen of these were definitely improved within 3 months.

The diet of the remaining 36 cases, 28 of whom had shown no improvement on the diet alone, and 8 no improvement with the cereal supplement, was now enriched by a liquid concentrate of rice polishings.* 20 cc. were taken daily, divided into three equal portions before meals. This provided at least 1000 International Units of B₁, 250 units of B₂, and a large (but at present undetermined) quantity of the B₆ complex and the antipellagric factor. Of the 28 cases who had obtained no improvement on the diet alone 19 now became markedly better within 3 months. Five of the 8 who had obtained no noticeable benefit from the cereal supplement became free of most of their symptoms within a few months after the cereal was replaced by the liquid concentrate.

Twelve of the 67 cases obtained no significant benefit from our therapy.

In the group taking the liquid vitamin concentrate the first improvement noted was again the correction of constipation. This appeared within 2 to 4 weeks, and occurred in all of the 24 cases of this group who obtained any improvement whatever. Anorexia disappeared in 18 of this group, and dyspepsia in 20. Improvement in the feeling of strength and in general well-being was commented on by all of the 24.

A summary of the results obtained in this group of 67 cases is given in Table I. If this group is a fair sample it appears that approximately one-quarter of the cases of "functional" chronic gastro-intestinal malfunction can be relieved of most of their symptoms simply by providing a well balanced diet and stopping the use of laxatives. Other factors contributing to this improvement may have been psychological influence and the effects of generally improved hygienic circumstances resulting from regular medical questioning and examination. In two-thirds of the cases these measures were inadequate. In more than half the total number of cases definite general improvement was established only after the ingestion for some months of rather large amounts of supplementary vitamin B. The results obtained with the liquid concentrate argue against the importance of bulk or roughage in the diet or in the cereal.

A group of nearly 200 cases received the cereal supplement from the beginning. The records of 160 of this group are summarized in Table II. The forty odd remaining cases were omitted from the table because the records were incomplete; but the results appeared to be essentially the same as in those recorded. Table II does not include the cases in Table I. The age and sex distribution in all our cases is given at the foot of Table II. The statistical distribution of the results appears to be unaffected by either the age or sex of

*This concentrate was generously supplied us by the Vitab Products, Inc., Berkeley, the manufacturers.

the patients. It will be noted that essentially the same results were obtained whether the patients were treated in private practice or in dispensaries.

Relief of constipation was obtained most frequently. Next in order of frequency was relief from abdominal pain.

The order in which the symptoms were relieved in an individual case was the same in these groups as in the 67 cases discussed above: constipation (in most cases within 2 to 4 weeks), abdominal pain, appetite, headaches, the feeling of fatigue. "Gas" was again the most persistent complaint.

It may be noted here that the observations regarding constipation may be considered as objective ones. Certainly they are least influenced, as observations, by subjective bias. Yet it is precisely here that the most striking improvement was recorded in every group.

Two changes observed call for some additional comment. In 30 cases there was a notable improvement in the complexion. This clinical observation is interesting in the light of the later demonstration that the vitamin B complex contains at least two anti-dermatitis factors (14).

To our mind the most important improvement noted, and it is inadequately recorded in the table, was in the state of well-being. Six who were on the Relief Roll because they felt too ill or too weak to work, later voluntarily applied for work. A similar change was observed by Marks.

We obtained some evidence that continued ingestion of relatively large amounts of vitamin B is required. Eight patients were selected who had shown no improvement on the diet alone; 3 had become symptom free with the liquid concentrate, 5 with the cereal. After they had been free of symptoms for 3 months the vitamin supplements (liquid concentrate or cereal) were withdrawn. In every case the original symptoms returned within 3 months. On the resumption of the vitamin B supplement they again became symptom free.

In five cases who had become free of symptoms while taking the cereal the same weight of pure wheat germ was substituted for two months. This substitution gave approximately 50 per cent more B₁ at the cost of a large decrease in the other members of the B complex. In all five cases symptoms reappeared after one month and became worse. These disappeared again when the use of the cereal was resumed. This experience suggests that other components of the B complex besides B₁ are important in the alleviation of gastro-intestinal malfunction. A similar observation was made by Elsom.

We have had 3 cases of chronic diarrhea in which all the common causes had previously been excluded. One of these failed to obtain any benefit from the treatment described above, 2 were completely cured.

The history of one of the latter two cases briefly is as follows:

Male, aged 52, during the previous 18 months had had 3 to 6 bowel movements daily with the passage of considerable mucus; generalized abdominal pain, and tenesmus. He had lost 28 pounds and had become markedly anæmic. He was referred with a diagnosis of chronic, non-specific, ulcerative colitis.

One month on the diet alone, followed by 6 weeks with the cereal supplement brought no improvement. Within a month after the cereal was replaced by the liquid vitamin B concentrate progressive improvement

set in. Within 2 months he was having 2-3 semi-solid bowel movements daily, was free of abdominal discomfort, and had gained 10 pounds. After 5 months he was having one normal bowel movement daily, had gained another 12 pounds, his complexion was improved, and his former strength had returned.

The other case became free of symptoms on the diet with cereal supplement.

DISCUSSION

It is now well established that there are what may be called physiological variations in the minimum vitamin B₁ requirement of adults. The minimum quantity of this vitamin required to prevent beri beri increases with weight, metabolic rate (fevers, hyperthyroidism), exercise, pregnancy, lactation, and the extent of carbohydrate metabolism. Some of these relations have been incorporated in a quantitative expression by Cowgill (15).

The optimum amount of vitamin B, i.e. the amount which affords optimum growth in the young, good health and the longest postponement of senility in the adult, may be four or five times as large as the minimum amount required to prevent beri beri. Sherman and Ellis (16), measuring differences in rates of growth and in the postponement of senility at different levels of vitamin B₂ (G) intake, are of the opinion that the optimum amount was not attained in their rats with five times the minimum protective dose.

A valuable study of this point was made by Drummond (17). He maintained rats on a level of vitamin B intake slightly below that required for normal growth. These animals were compared with normals, over a period of more than two years. This slight reduction in vitamin B intake had a marked influence on the adult life of the rat. Though the animals on the deficient diet attained adult size in practically the normal time, only 38 per cent survived two years compared with 64 per cent of the animals who obtained the larger amount of vitamin daily. The females in the deficient series had 14 pregnancies compared with 94 in the normal series. Seventy-six were born in the deficient series, and of these 16 per cent survived one month, whereas in the normal series there were 635 born with 88 per cent surviving one month.

This difference between minimum and optimum levels of vitamin B intake also occurs in humans. None of the subjects of the present study showed signs of beri beri, polyneuritis, pellagra, or any other evidence of acute vitamin B deficiency. The improvement in gastro-intestinal function following the ingestion of large amounts of vitamin B showed that they were subsisting on a suboptimal vitamin intake. The factors enumerated above, which determine the minimum requirement of vitamin B, probably enter here also and also influence the optimum requirement.

The present study also brought out what may be called a constitutional factor affecting the level of optimum vitamin intake. Some individuals require more vitamin B for good health than others. Thus in our first series of 67 cases about 25 per cent were relieved of their symptoms simply by the cessation of the laxative habit, and the provision of normal servings of fresh vegetables, citrus fruits, milk and eggs. For a larger number of cases this simple regime was inadequate. These individuals required a richer vitamin B intake than is provided in the ordinary good

diet. At present we can only speculate on the reasons for this variation in the level of the optimum vitamin B intake.

Another point which warrants some emphasis at present is the distinction between the use of large amounts of the whole B complex and of highly purified single components. Vitamins B₁ and B₂ (G, flavine), and the anti pellagic factor nicotinic acid, are now available in the crystalline state commercially. There are indications from the experimental work on animals and in Elsom's and our observations on humans that in most cases the whole B complex is superior therapeutically to any single fraction. There is also the obvious and important economic reason for preferring the whole B complex as it is found in foods to any highly purified single component. In this connection we would draw attention to the usefulness of the cereal fraction we have employed. It is rich in the vitamin

B complex, palatable, available wherever wheat flour is made, and cheap.

SUMMARY

1. A study is presented of the treatment by a dietary regime of 227 cases of chronic gastro-intestinal malfunction. The cases reported were studied for not less than three months, most for more than a year, and some for as long as four years.

2. Marked benefit was obtained in nearly all of these cases from the continued ingestion of large amounts of the vitamin B complex.

3. We have interpreted this result as indicating the existence of a widespread, partial vitamin B deficiency in humans, i.e. that many, if not most, people require for normal gastro-intestinal function several times the minimum amounts of the vitamins required to prevent severe deficiency diseases such as beri beri and pellagra.

The Vitamin C Content of Certified Milk at the Time of Consumption

By

FRED V. WEST, Dr. P.H.

and

JOSEPH C. WENGER, B.S.

LOS ANGELES, CALIFORNIA

MANY investigators have contributed a vast amount of knowledge on the subject of the vitamin C content of milk. Most determinations, however, have been made immediately or very soon after the withdrawal of milk from the cow. This report involves a study of the actual vitamin C or ascorbic acid content of certified milk at the time it is consumed in the home.

The effects of breed characteristics on vitamin C in milk were not a part of the study. However, as indicated in the accompanying chart, our findings are in close agreement with those of Russel, Rasmussen (1), and others.

The feeding of the cows was carried out in the customary manner. When corn ensilage was discontinued there was no appreciable change in the vitamin C content of the milk. The addition of orange meal to the grain feed made no apparent difference in the

ascorbic acid content of the milk. The catalytic and oxidizing factors involved in the preparation of orange meal probably account for its lack of vitamin C value.

Practically all stages of lactation were represented in the 108 cows that were used in the study. The milk was drawn into stainless steel buckets, aerated and cooled to 38° F. and held in refrigerated stainless steel vats until 150 gallons of milk were collected which required an average of approximately 65 minutes. Samples of Guernsey and Holstein milk were taken from the regular run of milk between two and three a.m. on Mondays, Tuesdays and Wednesdays for a period of ten weeks, starting in January. Samples were collected at the dairy farm and were hauled without refrigeration to the laboratory, a distance of 20 miles.

In the study an effort was made to simulate a con-

dition that would cause a greater loss of vitamin C than would occur in the handling of milk in the average home.

Vitamin C determinations were made when the milk samples had reached the respective ages of 10, 34 and 58 hours. The samples were permitted to stand for 2 hours daily at room temperature and at all other times were held at 43° F.

The vitamin C determinations were made in the following manner: 10 cc. of milk were treated with 10 cc. of 16% trichloroacetic acid solution to precipitate the proteins and 6 cc. of 10% metaphosphoric acid solution to preserve the ascorbic acid. The latter precaution was taken to protect against losses through interruptions. The mixture was permitted to stand for 20 minutes after which the supernatant liquid was removed by centrifuging at 1500 R.P.M. for five minutes and decanting. The precipitated residue was not washed. Titrations were made with a standard solution of sodium 2,6 dichlorobenzenoneindophenol from which a stock solution was used for five days only. From the stock solution a fresh dye was made each day and standardized against a N 100 iodine solution and also against ascorbic acid (La Roche). A

total of 720 titrations were made. The accompanying graph indicates our finding.

The maximum permissible age of certified milk is 30 hours at the time of delivery to the consumer (2). In Los Angeles the milk from the dairy farm where the samples were taken is delivered at an age from 10 to 24 hours. Allowing 10 hours in the home for consumption, the maximum age of the milk would approximate 34 hours, at this age the average minimum vitamin C content of the Holstein milk would approximate 13.1 mg. per quart (262 international units) and that of the Guernsey 14.2 mg. per quart (284 international units).

The Council on Pharmacy and Chemistry of the American Medical Association state: "The claim that a food is valuable because of its vitamin C content should be permitted only if it provides a daily intake of at least 250 units of vitamin C" (3).

Therefore, the certified milk from the dairy farm where these samples were taken may be said to be "a valuable food because of its vitamin C content" if one quart of milk is consumed daily and the same standards of production continue. Because of the great variation in the vitamin C content between different types of milk, no claims should be made for any milk unless such claims are substantiated by laboratory determinations.

The milk used in this investigation may be considered as a highly desirable safety valve in cases where the infant or child has been deprived of citrus fruits or their juices. No attempt, however, should be made by milk producers to discourage the use of orange or lemon juice.

SUMMARY

720 titrations in determining the vitamin C content of certified milk from 108 cows indicate that this milk on which the determinations were made may be considered "a valuable food because of its vitamin C content."

Cyst of Gastro-Colic Omentum

By

DAVID B. FISHBACK, M.D.
PHILADELPHIA, PENNSYLVANIA

WHILE there are comparatively numerous reports of cysts of the mesentery, there are not many recorded cases of cysts in the omentum. This is a report of an enteric cyst in the gastro-colic omentum.

Four main varieties of cystic tumors appear in the

peritoneum, mesentery and omentum: Lymphatic or chylous cysts, enteric cysts, urogenital cysts and dermoids or teratoids.

Enteric cysts form single or multiple large or small cysts lying usually along the lower end of the ileum, in the wall of the intestine, at the point of Meckel's diverticulum (Boh), in the mesentery, or near the

Fig. 1. Enteric cyst anterior to and attached to gastro-colic omentum between stomach and splenic flexure of colon.

Fig. 2. Low power magnification 100X. Cyst wall showing single layer of endothelial cells at top, stroma, and intestinal acini in lower portion.

navel (Wyss) When originating within the muscular wall of the intestine, they usually remain connected with this organ and are enclosed by a muscular wall. The cavity is usually single and the contents are mucinous, colorless, yellowish or brownish fluid. The wall resembles that of the intestine, and may contain smooth muscle, mucosa, crypts, lymphoid tissue, and a lining of cylindrical or cuboidal or stratified epithelium (Colmers). The epithelium may show papillary proliferation. Both cylindrical and squamous cells may be found in the same cyst.

Roth and Hennig found a large cyst in the mesentery and one in the posterior mediastinum, both in infants. Sanger and Klopp, in a newborn infant, found 5 cysts, in the walls of two of which were portions of liver tissue. Honl has reported 2 remarkable cases of multiple enteric cysts in which there were 37 and 89 small cysts lined by intestinal mucosa (1).

B. Schwarzenberger, in 1894, reported a case of multiloculated cyst of the omentum, discovered at operation, in which there was clear fluid, Sp. Gr. 1016 (2).

During life, large omental cysts may simulate a loculated tuberculous peritonitis or an ovarian cyst. Other conditions that must be considered in the diagnosis are: Lipomata, mesenteric and pancreatic cysts, aortic aneurism, and large cysts of the spleen (3).

In this case reported, had the cyst enlarged, it would have produced pressure on the stomach or colon, with resulting symptoms.

This case is from an autopsy done at the Philadelphia General Hospital.

The patient was a female, black, age 49. The clinical diagnosis was complete perineal tear, with vesico-vaginal and recto-vaginal fistula, arteriosclerosis and myocardial degeneration. Abdomen showed a small umbilical hernia. There were no palpable masses and no areas of tenderness. The cyst was not diagnosed during life.

Autopsy Findings (Anatomical Diagnosis): Parenchymatous degeneration of myocardium; pulmonary

Fig. 3 High power magnification 200x Cells of columnar epithelium arranged in acinar formation. Stroma shows numerous fibroblasts.

emphysema, congestion, edema; chronic atrophic splenitis, arteriosclerosis of spleen; pyelonephritis, nephrosclerosis; urinary bladder, acute suppurative cystitis

secondary to vesico-vaginal fistula; recto-vaginal fistula; congestion, cloudy swelling and arteriosclerosis of liver; omental cyst.

Omentum: In the gastro-colic omentum, between the stomach and the splenic flexure of the colon, there was a circumscribed cystic mass, measuring 5 x 4.5 x 4 cm. The cyst was spheroidal in shape and unilocular. The cyst wall was semi-transparent, about 1 mm. in thickness in most areas, slightly thicker in other areas. From the outer surface it appeared light bluish purple in color. The substance within the cyst was gray and semi-solid, gelatinous in nature. The cyst did not seem to produce any pressure on the surrounding viscera. There was a general ptosis of the intestines, the transverse colon being below the level of the umbilicus. The cyst extended from the stomach to the splenic flexure of the colon.

Microscopically, there is a single layer of endothelial cells lining the cyst wall. The stroma shows mucoid degeneration and contains many fibroblasts. Cells of columnar epithelium are arranged in acinar formation. They resemble bile ducts.

Because there are some intestinal acini in the wall of the cyst, this is an enteric cyst derived from the dilated acini of a heterotrophic enteral gland (4).

SUMMARY

Because of its rarity, an enteric cyst of the gastro-colic omentum is reported, having been discovered at autopsy. This should be considered in the differential diagnosis when a patient is presented with a mass in the upper abdomen.

The author is indebted to Dr. Lawrence W. Smith for assistance in histologic diagnosis.

The Early Diagnosis of Non-Tropical Sprue, with a Note Upon Its Familial Incidence*

By

G. LOUIS WELLER, Jr., M.D.

WASHINGTON, D. C.

NON-TROPICAL sprue is a disease which is diagnosed both less frequently and later than should be the case. Perhaps explanation for this fact, in part, is the similarity which exists between the onset of sprue and mild enteric infections. More important, however, seems the fact that the clinical picture of early sprue is so markedly different from the usual or classical accounts of this disturbance. In early sprue the outstanding characteristic is increased frequency of bowel movement. In the classic type of sprue the very frequent bowel movements are accompanied by

emaciation, anemia, fatty stools and a host of other general abnormalities. In early sprue prolonged general discomfort of the patient is unnecessary, and for this reason it seems that this disease is worthy of prompt recognition and therapy.

As far as is known, the family reported herewith is the first one on record. A priori, if sprue is the result of insufficient production of some specific hormone, then as in the case of diabetes mellitus, it is not unusual to find a high familial incidence in some cases. Increased frequency of diagnosis probably will bring to light many more of these families.

*From the Department of Medicine, School of Medicine, The George Washington University, Washington, D. C.
Submitted October 20, 1935.

LITERATURE

Although Snell reports that more than 100 cases of non-tropical sprue are on record, practically all of these cases are of the classical type. As discussed by Hanes and McBryde, for instance, they all include steatorrhea with or without bone changes and anemia. The cases of the series reported here differ from these classical cases in that the abnormalities are confined chiefly to the intestinal tract and there is no essential change in other organs nor systems.

CASE ABSTRACTS

Case 1. L. T. M., a 30 year old white male, was seen first in September, 1936, complaining of "nervous diarrhea" for the past three to four years. During childhood and until onset of the present illness the patient's bowel movements were normal. No history of residence in tropical climate. No other members of family troubled with similar type of disturbance.

Since onset of the illness the patient's bowels have moved three to five times daily. There is always considerable gas, frequently the stools are liquid and bowel movements must occur quickly once the impulse has been noted. Occasionally, for a period of one or two days, movements seem to return to normal. When diarrhea is maximal then there is a rather continual "nervous," "unsettled" feeling in the epigastric and mid-abdominal regions.

Physical examination revealed no essential abnormalities of the eyes, heart, lungs, chest and abdomen. Erythrocyte, leucocyte and hemoglobin values were normal. Fluoroscopic examination of the gastro-intestinal tract revealed rapid peristalsis and very little of the barium remaining in the terminal portion of the bowel at the end of five hours. Basal metabolic rate determination was -18.

Since 2-1 cc. ampules of a concentrated liver extract have been administered, at approximately ten day intervals, the patient has been practically free of the disturbance. The bowel movements have been kept to one, occasionally two formed stools daily. There was freedom from the nervous uneasy feeling in the epigastrium, and the patient was able to have bowel movements at his leisure.

Case 2. B. W., a 36 year old white female, first noted the onset five or six years ago of "bilious-like spells." Beginning at first as a "sick headache," each attack became increasingly more severe. The earlier attacks were characterized by onset of chills, then a nauseated feeling and finally a "terribly weak" feeling before the bowels moved. On most occasions the patient vomited and had no bowel movement simultaneously.

As the attacks progressed bicarbonate of soda was taken with increasing frequency for the uncomfortable feeling in the abdomen. One-half teaspoonful of milk of magnesia caused marked exacerbation of the diarrhea, the bowels moving approximately every five minutes for half a day.

With sedatives and relief of a certain degree of financial stress at home, the patient's condition improved somewhat with the years. Symptoms which have persisted, however, include rumbling, gushing sounds, and sensations in the abdomen and an uncomfortable sensation in the abdomen after eating. Occasionally there was constipation for a period of 24 hours; this, in turn was followed by 2 days of normal bowel movements during which time all traces of rumbling sensation disappear. The periods of constipation are believed by the patient to be due to omission of fruits and vegetables from the diet and the use of toast, macaroni, potatoes and fresh bread.

Bowel movements were noted as "bright orange" during periods of diarrhea, but are dark brown during periods of normal bowel movements. Rather frequently canker sores occur in the patient's mouth, but the frequency of occurrence of these has decreased since extraction of practically all the teeth.

Physical and laboratory examinations were essentially

normal. Fluoroscopic examination of the gastro-intestinal tract showed increased rapidity of movement of the barium meal. Specimens of stool revealed no definite abnormalities. More recently a mild hypochromic anemia has developed.

The familial aspects of this case are as follows: The patient has 3 sisters and 2 brothers. One sister is suffering from "colitis." Her symptoms are more severe than are those of our patient. She experiences more pain and more feeling of "congestion," while bowels move regularly three times daily.

The remaining sisters are living and well and their intestinal tracts apparently function normally. However, the son of one of these sisters, has "stomach trouble." His symptoms are similar to the above and hospital study has revealed no organic disease.

One of our patient's brothers also has "stomach trouble," characterized particularly by increased frequency of bowel movements. X-ray studies likewise revealed increased rapidity of passage of barium through the intestinal tract.

A second brother is living and well. Of the patient's four children, the two daughters, aged 9 and 14, are perfectly normal. One son, four years of age, complains at regular intervals of abdominal pain and discomfort. Symptoms persist for one week, then are absent for one month, on the average. Even during "quiescent" intervals the child never has less than two bowel movements daily. The mother emphasizes the fact that she "never remembers giving the child a cathartic."

A second son, 16 years of age, has experienced at irregular intervals, severe attacks of abdominal pain and diarrhea, but his mother has been unable to have this condition studied further.

Case 3. S. D., an eighty year old white female, noted rather insidious onset of diarrhea. Dietary intake was for the most part voluntarily limited, but certain additional restrictions were the result of attempts to control a discomforting arthritis. There were few symptoms associated with onset of the diarrhea. For the most part, the bowel movements were watery and occurred as often as eight to ten times in 24 hours. Powders given for the control of diarrhea were only partly effective, but there was a good response to codeine sulfate. Oral liver extract in moderate doses, together with an increased intake of beef and liver has relieved the diarrhea somewhat. Intramuscular liver extract plus the more normal diet made both powders and opium derivatives unnecessary.

Gastro-intestinal X-ray examination, done prior to the control of the diarrhea, revealed the usual increased rapidity of passage of barium through the gastro-intestinal tract together with smoothing of large bowel markings.

Case 4. A. M., a 42 year old white male, was seen first in July, 1937, because of what appeared to be a mild attack of gastro-enteritis. The symptoms subsided within several days following the use of bismuth subnitrate and codeine sulfate. Two weeks later the patient noted a recurrence of the diarrhea with semi-formed stools. There was no steatorrhea, nor dietary change which influenced the frequency of bowel movement. Additional symptoms included a generalized uncomfortable feeling throughout the abdomen and at times this feeling became very marked only to be relieved by movement of the bowels. Gastro-intestinal X-ray series showed increased rapidity of passage of the barium through the small and large intestines. Following intramuscular injection of 2-1 cc. ampules of a concentrated liver extract, the patient was entirely relieved of symptoms for a period of ten days. Subsequent injections of 1 cc. liver extract have been administered at intervals from eight to ten days with complete freedom from symptoms and intestinal abnormality.

DISCUSSION

The significant clinical characteristic of non-tropical

sprue is increased frequency of bowel movement. In the absence of fever, blood or mucus in the stools, it is the diagnosis of choice until proved otherwise.

The diagnosis of early non-tropical sprue, or preferably early sprue occurring in temperate climates, is made by relying practically entirely upon symptoms elicited by the case history. Increased frequency of bowel movement, abdominal discomfort, passage of liquid or semi-solid stools, exacerbation of the condition after ingestion of certain foods all are points of especial importance in the diagnosis. Abnormalities such as gastro-intestinal lesions, anemia, or stentor-rhea, if obtained during laboratory study of the case are indicative of the classic or fully developed stage of the disease.

The onset of diarrhea apparently may occur at any age in or beyond childhood. The disturbance seems most characteristic, however, when it occurs in young adults. The patients usually seem to have experienced sporadic attacks before the disturbance begins in earnest. Once the disease has begun, the abdominal discomfort becomes a common feature.

There is general agreement among patients with this disease that a sensation of inward abdominal nervousness is a prominent feature. Occasionally this is relieved by the bowel movement; occasionally it is accompanied by an additional sensation of rumbling and gushing within the abdomen.

In all of the cases here reported the stools are characteristic. For the most part they are soft or watery and light yellow in color. It is to be noted that this appearance is in sharp contrast to the oily, greasy, foamy, foul smelling stools of sprue in the advanced or classic stage. In the early sprue cases, despite the rumbling sensations in the abdomen there is very little discomfort from the passage of gas by bowel, and the patient only rarely complains of foul smelling gas.

Exacerbation of the disturbance after certain foods, makes one think of the possibility of an allergic condition being responsible for the disturbance. Undoubtedly this reaction to certain foods does occur, and perhaps is associated with onset of the disturbance originally. However, substitution of beef, liver, and buttermilk for vegetables in the diet result only in slight improvement if liver extract is not given. The fact that vegetables are tolerated well after the intestinal disturbance has been eliminated by injections of liver extract, makes food allergy only a supplemental factor.

The differential diagnosis of early sprue involves chiefly disturbances localized to the gastro-intestinal tract. If the patient is seen soon after onset of the disease a low grade enteritis from the dysentery group of organisms or from amebae is foremost among the confusing diseases. Usually with inflammation of the intestine, in these latter cases there occurs fever of varying degrees. Also blood and pus soon appear in the stools if the inflammation is very marked. Cultures of the stools reveal the offending agent. If the enteritis is the result of infection with protozoa then microscopic examination of fresh specimens of stools will reveal the invading agent. Sigmoidoscopy, in addition to allowing inspection of the mucosa of the lower bowel frequently also facilitates collection of material for examination.

Carcinoma of the intestinal tract must be ruled out before the diagnosis of early sprue can be made. It seems not unlikely that a gastro-colic fistula for

instance, resulting from carcinoma could simulate early sprue for a period of time. As the carcinoma progressed, its presence undoubtedly would become clearly evident. Gastro-colic, gastrojejunal or other fistulae as the result of surgical manipulations within the abdominal cavity usually are readily enough recognized from the history of abdominal operation and the findings upon fluoroscopic examination.

The progress of barium taken by mouth and observed beneath the fluoroscope is exceedingly rapid in sprue, once it has left the stomach. Usually in only three to four hours the head of the column of barium is found in the sigmoid. Not infrequently moderate amounts of the barium have been eliminated by this time.

TREATMENT

As regards treatment, liver extract in concentrated purified form is very effective if administered intramuscularly. Relief comes almost within two to three days after the first injection. In some instances, particularly very mild cases of early sprue, constipation results from administration of the liver extract. Variations in the amount of liver extract required can be met only by trial adjustment of both the amounts injected and the frequency of injection. Ordinarily one to two cc. of concentrated liver extract will protect against the disturbance from five to fifteen days. Within these limits it is well to let the patient judge the frequency of injection by the sensations which appear in the abdomen, together with frequency of bowel movement and consistency of the stools.

FAMILIAL INCIDENCE OF SPRUE

Insofar as can be judged from the literature the familial incidence of sprue has received very little attention. It is believed that this is the case because the diagnosis has been made in so few instances outside the tropics that there has been little inquiry into its familial incidence. In the family of our second patient, who is a white female, the men seem to have suffered more than the women. However, a sister of the patient who undoubtedly has sprue, has been diagnosed as having "colitis." A brother of the patient has approximately the same type of disturbance as the patient and while the patient's two daughters are perfectly normal her two sons have practically the same type of disturbance as their mother. The fact that the patient's sister and brother remained in Massachusetts while the patient came to Washington at the age of eight and has raised her family here seems to have made little difference in the development of the disease in the members of this family. It is interesting to note also that the son of one of the sisters who is well, has the same type of disturbance as has our patient. Thus from the standpoint of heredity the males and females seem to stand equal chance of transmitting the disease and of contracting it themselves.

SUMMARY

The clinical features by which early sprue as it occurs in temperate climates is recognized, are presented and discussed. It is emphasized that the diagnosis in the early stage is dependent entirely upon subjective sensations. In the absence of any other organic lesion, reliance is placed upon the history of increased frequency of bowel movement, the sensation of abdominal distress, and the exacerbation in in-

testinal peristalsis after ingestion of certain foods. In addition the examination of the stool reveals only soft material or partially undigested foods, but never blood nor pus. A final point in the diagnosis is that of increased mobility of the barium through the intestinal tract so that it reaches the sigmoid at the end of three to four hours after ingestion. Liver extract intramuscularly, repeated at varying intervals, is practically specific treatment.

A case is reported in which sprue is present in a large proportion of the members of that patient's

family. This is believed to be the first evidence of familial incidence of the disease in temperate regions. Both males and females alike seem susceptible to the disease, but it seems that the disease may be transmitted to her offspring by a female who remains well.

An Unusual Case of Chronic Duodenal Ulcer

By

WILLIAM FITCH CHENEY, M.D.
SAN FRANCISCO, CALIFORNIA

CASES of chronic duodenal ulcer have been reported so frequently, at medical societies and in medical journals, that repetition has become boring. Nevertheless the following patient presents such a typical account as regards chronicity, periodicity, rhythmic sequence of events and character of symptoms, such an exceptional variety of possible complications and such a complete picture of the methods of treatment commonly employed, both medical and surgical, that his story seems worthy of special report. Furthermore it raises once more an old question as to whether duodenal ulcer in some instances is ever cured by any plan of management, to the extent that the patient can be assured his symptoms will never recur.

I. *History:* Mr. W. H. M., aged 47, first seen by the writer in August, 1937, began to have trouble with his stomach during the Winter of 1913-1914. He saw no doctor at that time but learned to obtain relief by taking soda. In July, 1914, he had for the first time a severe hemorrhage and vomited large quantities of blood; but recovered after a month of rest in bed. He was better for a while after that but during the Winter of 1914-1915 he had again more or less constant pain in his stomach, although he still sought no professional advice.

In the latter part of April, 1915, however, there occurred a sudden severe attack of abdominal pain, diagnosed as appendicitis by the physician who was summoned in the emergency. He was taken at once to a hospital; and when hot applications to the abdomen all during one night gave no relief, the abdomen finally was opened next morning to remove an inflamed appendix. Much to the operator's surprise, however, he found instead a perforated duodenal ulcer. This was repaired, a gastro-enterostomy was done, and the patient recovered after a lengthy convalescence. But after he returned home more or less constant distress from "gas pains" reappeared and persisted again during the Winter of 1915-1916.

In the Spring of 1916 he consulted a number of different doctors, some of whom advised further surgery, some medical treatment. He finally accepted medical advice, and adopted a routine plan of treatment by diet and alkalis. On this he improved and

continued to feel so much better during the Summer of 1916 and the Winter of 1916-1917, if only he watched his diet, that in April, 1917, he enlisted in the army. He was never sent abroad but in camp in this country, he felt fairly well so long as he could get the character of food required.

In February, 1918, because of recurrence of his stomach trouble, he was sent to the Letterman General Hospital from the School of Aeronautics in Berkeley. The army doctors at the hospital advised immediate operation; and because he declined he was discharged from the Service in April, 1918.

From the latter date until November, 1920, he was continually distressed but able to attend to his work as an automobile salesman, if he observed his diet and took his alkaline powders as prescribed. Then finally he became so much worse that at that time he went back to the Letterman Hospital and submitted to operation as advised. He was told afterward that the gastro-enterostomy was not functioning properly and that below it a lateral intestinal anastomosis had been done. After the operation his condition was variable, with periods of complete comfort and then for no reason at all a recurrence of all symptoms.

In August, 1921, he went to the Mayo Clinic and came under the service of Dr. George B. Eusterman. There he was put to bed for a month and given a routine Sippy course of treatment by milk and cream and powders; but in spite of that, as soon as he got up and moved about, his pains recurred. He left the Mayo Clinic about December 1, 1921, and returned to his home on this Coast.

Nevertheless he was distinctly better after that experience and continued very active for some time so far as business was concerned. But his trouble recurred from time to time in spite of milk and cream diet until finally in May, 1924, because his suffering had again become so intense, he returned to the Mayo Clinic. There in May, 1924, another operation was done by Dr. Will Mayo and Dr. Donald C. Balfour. He was told that the gastro-enterostomy was taken down and the normal continuity restored, by which food was sent through the pylorus and the duodenum. After that operation his condition was much improved, he

had no pains, food tasted good and he felt better than for years previous. He returned home and went back to work.

Then, just sixty days after his operation in May, in August, 1924, his duodenal ulcer perforated again, without warning. He was taken at once to a hospital in San Francisco, the perforation closed and the gastro-enterostomy restored. After this operation comparative peace prevailed for over ten years. He managed to get along with a fair degree of comfort by careful diet and taking complete rest whenever his pains became very acute.

But once more in February, 1936, his condition again became so intolerable that he entered the Veteran's Hospital at Fort Miley, in the effort to obtain relief. This time a new plan of treatment was advised and he was given a series of injections of Larostidin, thirty-six in all. These caused such improvement and such relief from pain that he was discharged cured in April, 1936.

Unfortunately the cure did not last long and in two weeks he was suffering as much as ever. After trying to get along at home for another two weeks, he returned to Fort Miley Hospital four weeks after his first dismissal. Here another series of injections of Larostidin was given, 24 in all this time, with again complete subjective relief. He was discharged the second time in May, 1936, but advised to continue his "shots" at home. In spite of them, however, his pains recurred more or less constantly after he left the hospital the second time. So in February, 1937, he went back to the hospital for another series of injections of Larostidin. He does not know how many he had altogether during his visits there and at home but knows there were over 100. He was discharged the third time in April, 1937, as usual, much better after his rest and injections.

But in spite of all that had preceded, he had another severe hemorrhage on May 31, 1937, and had to be taken back to the Fort Miley Hospital in an ambulance. After routine treatment by ice-packs, discontinuance of food, etc., the bleeding stopped. Ultimately he was placed again on the Sippy diet and alkaline powders and recovered to such an extent that he could be dismissed in June, 1937. The surgeons at this last admission refused to do any further operating.

The above story was obtained from the patient on his first visit to the writer in August, 1937. Although he was then restricting his food to the usual non-residue diet which he had learned by long experience and was taking Upjohn's Nutrochloric tablets regularly, he had much pain not completely relieved by either. He suffered particularly at night, never slept over two hours at a time and when roused by pain he had to take milk or several tablets to get relief.

II. *Physical Examination* showed nothing abnormal except the numerous operative scars in the abdominal wall. The patient's weight was 172 lbs., and the tendency was to gain because of the large amount of milk and cream constantly consumed to relieve pain. The heart was normal in rate, rhythm and sounds and the blood pressure 120 systolic and 70 diastolic.

III. *Laboratory Findings:* There was a moderate secondary anaemia, with hemoglobin 65 per cent and red cells 4,000,000. The Wassermann reaction was negative. The stool showed no occult blood. The urine was cloudy and turbid, alkaline in reaction, with a heavy sediment of phosphates.

Stomach contents removed at 9 a. m., with the patient fasting since midnight in spite of pain, were 60 cc. in amount, with no blood gross or occult, but with total acidity 65 and free HCl 40. After an alcoholic test meal the total acidity in fifteen minutes extractions ran 18, 42, 44, and 50; and the free HCl 8, 26, 28, 34. This analysis is unusual if a gastro-enterostomy is functioning properly, for then regurgitation usually produces an achlorhydria.

IV. *X-ray Films* of the stomach and bowel revealed some interesting details. The stomach filled readily in spite of slight spasm at the cardia. As soon as it had partially filled the cavity, the barium ran through the gastro-enterostomy opening into both sides of the loop of small bowel; but some of it passed also through the pylorus and duodenal cap, both of which were obviously deformed. When the other loops of small bowel were well filled, there was a definite puddle formed in the dilated loop to the left of the stoma, and some fixation was observed at this level, probably due to obstruction by post-operative adhesions below this dilated loop. At six hours the stomach was empty, all the dilated loops of small bowel were likewise empty and the barium had reached the hepatic flexure.

A second barium meal was given twenty-four hours after the first. This showed the stomach completely filled before the gastro-enterostomy began to function. Confirmation was obtained that food passed also through the deformed pyloric end of the stomach and the duodenal cap.

Several suggestive facts were thus brought out by this X-ray examination: (1) There was definite evidence furnished of an old chronic duodenal ulcer with deformity. (2) In spite of previous perforations and operations for repair, the pyloric orifice and duodenal cap were not obstructed but permitted some of the barium at least to leave the stomach by this route. (3) There was spasm at times at the gastro-enterostomy orifice that delayed the exit of stomach contents through it; explaining the presence of hyper-acid secretion in the fasting contents and the failure of regurgitated duodenal contents to keep the stomach neutral. (4) The presence of slight obstruction about five inches beyond the gastro-enterostomy opening with laking of the barium at that point in the loop, might be due to post-operative adhesions or to the lateral anastomosis that the patient said was performed at the Letterman Hospital in November, 1920; but this did not cause a six hour delay.

TREATMENT

By regulation of the kinds of food to be taken, and the hours at which it was taken; by decreasing the number of nutrochloric tablets at night; by allowing instead a minimum amount of a powder containing soda, magnesia and bismuth; and by giving a few drops of the tincture of belladonna three times a day, the patient was afforded relief from pain and comparative comfort, his urine became clear and neutral or slightly acid and he obtained more hours of sleep at night than for weeks before. But the chronic duodenal ulcer remains and it is realized that exacerbation of symptoms or another complication may occur sooner or later in spite of treatment, as has happened repeatedly heretofore.

further proof of what has been repeatedly asserted that in certain instances a chronic duodenal ulcer continues to be a menace no matter what plan of treatment is employed in its management.

A Case of Ulcerative Colitis with Unusual Complications

By

H. N. TAUBE, M.D.

A REVIEW of the American Literature of the past ten years fails to reveal a case of ulcerative colitis complicated by acute appendicitis. Such a case is being reported. Moreover, the diagnosis was made preoperatively and surgical treatment instituted with satisfactory improvement in her primary condition. Several other unusual complications that developed warrant attention.

Mrs. C., age 47, an Englishwoman, was first seen on October 29, 1935, with complaints of 1. Diarrhea and bloody stools, duration two years; and 2. Loss of weight and strength, duration six months. Family history negative; past medical history negative; personal history negative. Functional enquiry—Head and Neck—In 1934, a great many ulcers developed on the tongue that disappeared after one month. Respiratory system—negative. Cardiovascular System—patient tires readily, ankle edema at night. G.U. System—negative. Menstrual history—periods were scanty for the past year (1934) and ceased in August, 1935. Patient is unstable and worries a great deal. Her best weight was 104 pounds; her weight at time of examination was 78 pounds.

HISTORY OF PRESENT ILLNESS

The patient states that for years she would move her bowels with the slightest excitement, worry or emotional upset. In July, 1933, she complained of severe pain around the navel after eating blueberry pie. This pain was soon followed by frequent small, mushy, gassy movements, containing no obvious pathological products and were accompanied by cramps. The diarrhea persisted and was not related to food intake.

In the Spring of 1934, bright red blood, mucus and food began to appear in the stools. At this time, the patient was having seven or eight bowel movements daily. From the very beginning, the patient began to lose strength and weight and was becoming paler. In March, 1934, she was seen by a physician and was hospitalized. There a diagnosis of ulcerative colitis was made. This diagnosis was based on a sigmoidoscopic examination and X-ray. She improved after being on a bland diet, colonic irrigations bi-weekly and a transfusion. However, her bowel movements not only increased to twenty to twenty-four daily, but became watery or mushy with much blood and clots in them, and she developed tenesmus. For the past six months, the patient had noticed that her ankles were swollen in the evening and were normal in the morning. This was associated with shortness of breath on exertion. Her memory was becoming poor, and she was mentally slow, and obviously apathetic.

PHYSICAL EXAMINATION

The patient was a white female, looked about 55 years of age, malnourished, pale and stared into space. **Head and Neck**—Eyes negative except for marked pallor of the conjunctiva. Upper and lower plates. Tongue large and atrophic at the edges. Few small glands in the left anterior cervical fossa. **Chest**—thin-walled and atrophied

breasts. No axillary adenopathy. Respiratory system—negative. **Cardiovascular System**—Blood Pressure—134/80. Pulse—80. Heart—essentially negative except for hemic murmurs at all the valve areas. Radials—early arteriosclerosis. Temperature—99.4. **Abdomen**—thin-walled, moves freely, mild tenderness in the right lower quadrant. Liver—palpable one to two fingers. Spleen—not palpable. Bowel was squashy and peristalsis was audible. The descending colon was cord-like and not tender. **Rectal**—marked external hemorrhoids, spastic sphincter and rectum. Rectum—contained no feces but old blood. **Extremities**—negative. Nervous system—essentially negative. **Fluoroscopy of chest**—essentially negative. **Sigmoidoscopic examination**—mucosa was very granular and bled from multiple pin-point ulcers. The bowel wall was very spastic. No polyps were seen.

Provisional diagnosis:

1. Chronic ulcerative colitis
2. External and internal hemorrhoids
3. Secondary Anemia—nutritional
4. Malnutrition

The patient was admitted to the hospital on October 30, 1935; her weight at this time was 78 pounds.

Laboratory findings—Urine—Specific gravity 1018; Albumen +; Sugar negative; Microscopic negative. Hemoglobin (Sahli) 48% or 6.8 gms. Red blood count 3,900,000; White blood count 6,250; differential normal. Stools—occult blood four plus. Chemistry—Blood sugar 85 mgms.; N.P.N. 35; Cholesterol 160 mgms.; Van den Bergh 3 units. Serum proteins—Serum albumen 5.2; Serum globulin 2.6; Wasserman negative. Gastric analysis showed hypoaclidity with two hour meal. Serum agglutination against dysentery group was negative. Stool cultures were negative.

Barium enema revealed the following:

The colon filled up with extreme rapidity, taking only a few seconds after the first appearance of the barium in the rectum for it to reach the caecum. The entire colon from the splenic flexure down was almost rigid and showed no evidence of haustra. The colon capacity was very markedly reduced (350 cc.)

Treatment—The patient was put on a low residue, high vitamin diet with viosterol, cod liver oil, iron ammonium citrate 120 grains daily; codeine, morphine; and acroflavine 18000 retention enemas six ounces daily; transfusions of 150 cc. were given every two days.

Progress—Five days after admission to the hospital, the patient ran a fever of 102 degrees. The next morning, November 5, she was nauseated and vomited, although the temperature had returned to normal. The same morning she had five bowel movements. At 6 p. m. she vomited her supper. At that time, her temperature was 98 degrees and her pulse was 80. At 9 p. m. she complained of generalized cramps for the first time. The next morning the patient felt well but at 10 a. m. she vomited her breakfast. Her temperature was 99.2; pulse 80; W.B.C. 9,600; differential revealed 92% polymorphonuclears. On examination, there was found a soft, freely movable abdomen with some

tombress just above the right inguinal ligament. At that time, it was felt that we were dealing with either exacerbation of ulcerative colitis with a perforation or acute appendicitis. At 2 p. m. the temperature was 100.1 degrees; pulse was 78; W.B.C. 9,600; differential remained unchanged. At this time, there was definite rigidity in the right lower quadrant. In spite of her poor general condition and of the known rarity of acute appendicitis in ulcerative colitis, history and physical examination demanded immediate surgical intervention. At operation, an acute suppurative appendicitis was found. The appendix was about two and a half inches long and the size of a small sausage. The pathological report was acute ulcerative appendicitis; chronic appendicitis. The patient made an uneventful recovery, reaching a normal temperature by the fifth day. She was constipated for two days following the operation. A series of small transfusions of 150 cc. and a course of parathormone 7 units b.i.d. and calcium were given. On December 2, the patient was discharged, very much improved and having three or four soft formed bowel movements daily. Hemoglobin (Sahli) 72%; R.B.C. 4,400,000. Her weight was 76 pounds.

The patient remained well for the following five months until April 7, 1936, when following domestic trouble, diarrhea recurred. At the time of her second admission to the hospital, she was having twenty bowel movements daily, her weight being 75 pounds; temperature 99, pulse 90, Hemoglobin 70%, W.B.C. 7,200, R.B.C. 4,460,000. Urine was negative except for a trace of albumen. Stools were four plus occult blood and watery in consistency. Mentally the patient was very depressed. She was put on the same regime and began to improve. By the 16th of April, her weight was 77 pounds and stools decreased to six to eight daily. The patient was skin tested with polyvalent antidyenteric serum and on April 17, she was given 5 cc. of the diluted serum intravenously and on the 19th, 10 cc. Five days later, the patient had a severe serum reaction. Her face and tongue became swollen and a vesicular eruption covered the entire body. After being treated for two days, it disappeared. The severity of the reaction militated against continuation of the serum therapy. The patient remained fairly well until April 28th when her temperature rose to 102.6. Examination at that time was essentially negative; Hemoglobin 64%, W.B.C. 8,200, differential 70% polys. By May 1 her temperature had subsided to normal. No explanation could be found for this fever. On May 2, temperature again rose to 105.8; pulse 94, W.B.C. 8,000. Examination was essentially negative except for a slightly swollen tongue. On May 3, the temperature, after having fallen to 99.4 again rose to 105. The patient now began to complain of a sore mouth, difficulty in speaking and incontinence. The right maxillary gland was enlarged and the floor of the mouth was tender. The tongue was markedly swollen and covered with small ulcers. The temperature fluctuated between 99 and 105. Blood cultures were negative. A continuous intravenous, local hot irrigations and transfusions were started but

despite this, the patient became drowsy, listless and was unable to eat or drink. After May 5, temperature began to subside and the patient to improve. The tongue was still mildly swollen but she was able to take fluids. On May 12, the patient developed a croupy cough, inspiratory difficulty, and retraction of the infracavicular spaces was noticed. There was edema of the true and false cords to such an extent that the airway was almost completely obstructed. A tracheotomy gave the patient immediate relief. Bowel movements, however, were involuntary and there was still some difficulty with feedings. The tracheotomy tube was removed on May 28. On June 4, the left submaxillary gland became swollen and a mass was found on the right side of the trachea from which 20 cc. of pus was aspirated. Smear and culture from this material revealed staphylococcus aureus. The patient became irrational, drowsy and weak. Her temperature was 98.4 and pulse 100. Her position progressively became worse and she died on June 21.

Summary of the autopsy findings—The abdominal wall was extremely thin and there was almost complete absence of subcutaneous fat. The intestinal tract, oesophagus to anus, was removed in toto. The stomach was thin walled and atrophic. A duodenal diverticulum, the size of a thumb, was seen 16.5 centimetres from the pyloric end of the stomach and opposite the site of mesenteric attachment. The mucosa of the duodenum and jejunum was thinner than normal. The ileum for 53 centimetres above the ileocecal junction showed marked evidence of thickening and fibrotic changes. The entire mucosal surface was covered with pin-point ulcerations, giving the bowel a velvety appearance, similar to that seen in the large bowel. The appendix was absent but a senn was found at the caecal caecum. The caecum and the whole of the large bowel were much thicker than normal, particularly the distal 45 centimetres. This area was enormously thickened, apparently scarred and almost completely denuded of mucosa. The rest of the large bowel had a velvety mucosa showing many minute pin-point ulcers.

Histological sections made of various areas of the involved bowel revealed a chronic ulcerative enterocolitis lacking the picture usually observed in amebic dysentery and in no way suggestive of tuberculosis. Nothing of note was found in the rest of the abdominal viscera.

SUMMARY

A case of ulcerative colitis complicated by acute appendicitis has been reported. H. L. Bockus (1) reports two undiagnosed cases of ulcerative colitis complicated by acute perforated appendicitis found at autopsy. It is unlikely that this complication is as rare as one would gather from the literature. More frequent case reports would give one a better statistical insight as to its true occurrence.

Editorial

THE PAIN OF ULCER

IN 1912 Cannon and Washburn showed that there is a relationship between the contractions of the ball-balloon stomach and the pangs of hunger. These hunger contractions apparently travel down the stomach much as do the normal waves, but there are

some differences between the two types of activity. The hunger contractions tend to come in groups with fairly quiet intervals in between.

It has not been sufficiently recognized in the past that the recording balloon placed in the stomach serves to bring out and make visible the hunger contractions. When one studies under the roentgenoscope the really

any stomach of a ball shot placed any contractions they can be pictures, and then traces between the Only when a little has been inserted enough to (Gianturco).

After revision the pain of ulcer still remains poor are two main th it is due to conti ulcer, and the o hydrochloric of the evidence.

The well all stomachs are acid, the fact of an increase in up of pain, ulcer, at times the ulcer must be sensitivity go through to irritability pain is seen a break in the y with ulcer periods when shown (C).

That the fact that many persons acid in response to stimuli was secreted a valid reaction should be.

A puzzling pseudo-ulcer the morning it goes quiet patients with eating of a neutralized also in the enterotomy in which little of the stomach.

During an and P that rubbing of an ulcer caused typical was bei a relation e brought relief hydrochloric contraction the the pe Some m Hunger com often have from the co

empty stomach of a cat, with the outlines marked by lead shot placed under the serous coat, one cannot see any contractions or waves. They are so shallow that they can be detected only by taking roentgen motion pictures, and then measuring and plotting the distances between the markers in successive "frames." Only when a little air has been swallowed, or a balloon has been inserted, do the tiny contractions deepen enough to become visible to the unaided eye (Gianturco).

After reviewing the literature on the causation of the pain of ulcer the writer's impression is that much still remains poorly explained and controversial. There are two main theories to explain the distress: one, that it is due to contractions of the muscle overlying the ulcer, and the other that it is due to irritation by the hydrochloric acid of the gastric juice. The greater part of the evidence favors the second theory.

The well attested fact that even ulcer-bearing stomachs are often insensitive to the introduction of acid, the fact that there is no close relation between an increase in the acidity of the stomach and a flare-up of pain, and the fact that in the presence of an ulcer, symptoms commonly come and go, all show that at times the patient or the stomach or the floor of the ulcer must be insensitive, while at other times the sensitiveness must be so great that painful stimuli can go through to the brain. Such temporary increases in irritability probably explain the fact that typical ulcer pain is seen often in persons who have no demonstrable break in the gastric or duodenal mucosa. That patients with ulcer are more sensitive to pain during the periods when their symptoms are troublesome has been shown (Crohn).

That the pain is not always due to acid is shown by the fact that typical hunger distress has been seen in many persons in whom the stomach did not secrete any acid in response to food. The fact that under the maximal stimulus of an injection of histamine a little acid was secreted in some of these cases does not constitute a valid reason for "laughing off" this evidence. It should be faced squarely.

A puzzling fact is that patients with either ulcer or pseudo-ulcer will sometimes lose all of their pain on the morning of the first day of a vacation. Why should it go so quickly? It is hard to explain also why many patients with ulcer obtain perfect relief after the eating of a mouthful or two of food which cannot have neutralized much of the acid in the stomach. Puzzling also is the prompt relief that usually follows a gastro-enterostomy or a hemorrhage, especially in those cases in which little if any change is effected in the acidity of the stomach.

During an operation under local anesthesia, Dragstedt and Palmer made the interesting observation that rubbing, pinching, massaging or pulling on a scar of an ulcer on the anterior wall of the duodenum caused typical and severe pain. Curiously, while the pain was being produced in this way, the injection of a solution of sodium bicarbonate into the duodenum brought relief, and the subsequent injection of dilute hydrochloric acid caused the pain to return. Waves of contraction passing over the pars pylorica did not produce the pain.

Some men have maintained that ulcer pain is due to hunger contractions in the stomach or bowel, but others have failed to show any good correlation between the contractions in the stomach and the pain of

duodenal ulcer. Palmer (1927) found an association between hyperperistalsis and pain during only nineteen of 217 periods of observation: most of the time the pain came without any sign of unusual gastric activity. Against the contraction theory is the fact that the pain of ulcer is usually not rhythmic in character.

Wilson made the curious observation that the pain of duodenal ulcer tends to let up when gastric contents came through the pylorus into the duodenal cap.

Two of the most thought-stimulating and practically helpful articles on the causation of ulcers and pain are those by Langenskiöld (Skandinav. Arch. f. Physiol., 120:537-550, 1913) and Mann and Bollman (J. A. M. A., 99:1576-1582, 1932). They showed in dogs with fistulas that unbuffered dilute hydrochloric acid trickling through stomach and duodenum gradually exhausts the defensive powers of the mucosa, producing first distress, and later pain with reddening, irritation, and finally superficial ulceration. The defensive powers of the mucosa are much greater if food has been digested shortly before the experiment begins. Some of the split-products of food that are absorbed evidently help to protect the mucosa.

These studies explain why the pain of ulcer or pseudo-ulcer is best relieved when food is taken within a few minutes after pain appears. In many cases if the patient waits for an hour or two to secure food the relief obtained is imperfect or transient. Furthermore, when pain reappears some morning after a six months' interval of freedom, if food is taken immediately the patient may avoid going on into an attack lasting a month or more.

Apparently, food helps not only by neutralizing and diluting the acid but by protecting the mucosa. Much injury to an ulcer must be done at night when the acid probably irritates for an hour or more before the pain is severe enough to wake the patient. To avoid this some patients might do well to set the alarm to wake themselves at midnight to take a glass of milk.

The experiments of Langenskiöld and Mann and Bollman suggest that peptone might be a good substance to use in a drip for use at night. Some day surgeons may start such a drip immediately after making a gastro-enterostomy to protect the jejunal mucosa during the first, perhaps most dangerous week, when no food is being given to buffer the gastric acid.

In a number of patients it is certain that there is a relation between hunger pain and constipation, or the presence of gas in the colon. There are reasons for suspecting that some hunger pains felt in the epigastrium are due to difficulties encountered by the terminal segment of ileum in pushing its contents into the colon.

In some persons it may well be that the onset of hunger pain at 11 a. m. or 4 p. m. coincides with the peaks of cycles of increased irritability and activity in the whole digestive tract. Such rhythms have been demonstrated in animals and men.

That the pain of duodenal ulcer is not due to contractions of the overlying muscle is indicated by the fact that in man distention of the duodenum with a balloon is more likely to produce nausea, uneasiness, faintness, dizziness, and chilliness than it is to produce pain (Ivy, Bloomfield and Pollard). These symptoms are not seen commonly in cases of ulcer.

Obviously, several types of stimuli can produce pain

in stomach and duodenum, and the most usual one is probably irritation by the hydrochloric acid of the gastric juice. Always the factor of periodic or occasional increases in the sensitiveness of the stomach

or of the nervous system is an important one, and often it appears to be the decisive one in determining when an ulcer will produce pain.

Walter C. Alvarez, Rochester.

Book Review

Clinical Chemistry in Practical Medicine. By C. P. Stewart, M.Sc., Ph.D. and D. M. Dunlop, B.A., M.D., F.R.C.P.E. Price \$4.00, pp. 372, 38 figures and 15 tables. Second Edition, William Wood & Company, Baltimore, 1937.

THIS book constitutes a manual for laboratory diagnosis. It is not an elaborate text of biochemistry or of clinical diagnosis. Only those tests are given and discussed which are most simple and frequently used

in the clinical laboratory. The selection of tests is commendable and the explanation of the theory on which the tests are based is lucid. The second edition is a definite improvement over the first in that certain important omissions have been remedied. Although it is a very serviceable book, it is probably not as extensive in scope as some workers in this field might desire.

A. C. Ivy, Chicago.

DENVER, COLORADO

Servius, in 1615, recorded the first recognized case of total transposition of viscera in man. The writings of Aristotle show that he recognized two instances of transposed viscera in animals. Vehemeyer, in 1897, made the first X-ray observation.

In 1733, Calder described atresia of the duodenum. One hundred forty years later Theremin gave the first exhaustive review of the subject.

The earliest reference to obstetrical paralysis of the peroneal nerve was made by Bianchi in 1867. He stated, "these paralyzes usually follow difficult and prolonged labor, in which the foetus presents by the vertex and has to be extracted with forceps."

Soranus (98-112 A. D.) was the first as far as known to teach podalic version before the death of the child. Pare, in 1550, taught the technique.

That trained midwives were known among the Israelites is to be found in the first chapter of Exodus: "And the King of Egypt spake to the Hebrew midwives, of which the name of one was Shiprath, and the other was Puah." Reference is here made to the use of stools. The use of chairs or stools was an improvement over an outgrowth of sitting on the lap for in the thirtieth chapter of Genesis Rachael says, "and she shall bear upon my knees."

Bard of New York, published in 1808, the first American work on midwifery. Dewes, in 1797, gave private

lectures in obstetrics. In 1825, he published a noteworthy system of midwifery. In 1866, Hodge produced the first illustrated text-book on obstetrics. More than one hundred illustrations from wood-cuts appeared in the publication.

The largest ovarian cyst was reported by Spohn. The tumor was estimated to weigh 328 pounds. Ward, of San Francisco, operated on a patient weighing 309 pounds. She lived less than one hour after removal.

Kondoleon, of Greece, first devised an operation for elephantiasis of the extremities. It was not a curative procedure. There was tendency toward return of the enlargement.

Bard reported before the Chicago Gynecological Society the involuntary passing of a dermoid cyst from the anus at the time of a forcep delivery. The microscopic picture resembled that of a dermoid cyst of the ovary.

Rugae, in 1875, reported eight cases of fracture of the vertebral column following breech delivery.

Reference to adenomyoma of the sigmoid was made by Spencer in 1913: The term endothelioma was coined by Golgi in 1869.

Our knowledge of tuberculous tenosynovitis dates from the observations made by Olaf Acrel of Stockholm, in 1756.

Abraham Colles (1773-1843) Professor of Surgery in Dublin, wrote the original description of that fracture known as "Colles fracture."

Eugene Bouchut (1812-1892) introduced intubation of the larynx for croup.

CONNOTATIONS

By

H. J. SIMS, M.D.
DENVER, COLORADO

Lisfranc most probably was the first to amputate the rectum. He reported nine cases from 1828-1830.

Cardiospasm was first described by Purton in 1821, as idiopathic dilatation of the esophagus. Milulicz popularized the term cardiospas. He insisted that the symptoms were due to spasm of the cardiac sphincter at the lower end of the esophagus.

The space of Retzius was described by Retzius, a Swedish anatomist, in 1856.

Beau, as early as 1849, observed the relationship between gynecomastia and improper development of the sex organs.

Klob, in 1861, gave the first description of a right paraduodenal hernia.

Von Walther, in 1811, attempted to partially excise the scapula for a "spongy swelling." The patient died fourteen days later. In 1825, Mutzer successfully removed a portion of the scapula. Total excision of the scapula was performed by Syme of Edinburg, in 1856.

Burnt sponges were used by ancient Chinese in the treatment of goiter. The value of iodine in the burnt sponges has long been known.

Prolapse of the female urethra was described by Solingen, in 1732.

Phlegmonous gastritis was recognized by Varandalus, in 1620, and again by Barel, in 1656.

The term bezoar in early times was used to describe various types of concretions found in the stomach and in-

testines of animals. According to Persian manuscripts, these concretions were used as remedies during the Middle Ages. Trichobezoar is a term used to describe hair balls, commonly found in animals and occasionally in man. The largest trichobezoar in man was described by Davies. The mass weighed six and one-half pounds.

Von Langendorff and Mommsen, in 1877, described osteitis fibrosa cystica, mentioning shortening of the skeleton and occurrence of localized areas known as "brown cysts."

Early men ate the organs of animals because of their mystical value. They ate the raw pancreas of a sacrificed goat in the belief that the gods would give them luck.

CHAIKOFF, I. L., CONNOR, C. L. AND BISKIND, G. R.

Fatty Infiltration and Cirrhosis of the Liver in Depancreatized Dogs Maintained with Insulin. Amer. Jour. Path., XIV, 1:80-101, Jan., 1938.

It has been shown previously by Chnikoff and associates that depancreatized dogs treated with insulin survive for long periods of time when maintained on a diet adequate in calories, proteins, salts and vitamins, but lacking pancreas. But under such conditions a number of pathological changes occur in the animals; bilateral cataracts, disturbances in the blood lipids, especially a fall in the cholesterol esters, and, of particular note, there is a deposit of large amounts of fat in the liver. When pancreas is added to the diet these changes in the tissues are prevented.

The present study concerns the anatomical changes in the fatty livers as seen at varying intervals of time after pancreatectomy. Fat deposition may occur early and may last for a long time but finally a regression of the fat content in the liver takes place. In two dogs living 4 and 5.5 years respectively the fat content had returned to levels close to normal. In 49 dogs studied the livers showed essentially two types of lesions. The first occurred in association with the early infiltration of the fat, while the second change appeared most characteristically in those livers in which a regression of the fat had taken place. Such livers showed an extensive periportal fibrosis with irregular lobulation indicative of cirrhosis. Thus the depancreatized dog provided a new method for the production of experimental cirrhosis. This occurred as a final stage in response to a fatty infiltration of long standing in the liver. Infection seemed to play no part in the production of the cirrhosis, and there were no instances of obstruction in the extrahepatic bile passages found at autopsy. The fat first appeared, after pancreatectomy, in scattered cells within a lobule and slowly extended

outward from the central vein. This was followed by a progressive hyaline atrophy of the whole lobule. The process was slow and stimulated an evascular fibroblastic proliferation. A few lymphocytes and plasma cells were present. Strands of connective tissue then passed about other peripherally located cells, isolated them, and made the process progressive. The time element in the development of the cirrhosis varied in different dogs. The greatest degree was found in a dog living 2.6 years after pancreatectomy. The earliest signs of fibrosis were found only after 1.5 years had elapsed.

ROZENDAAL, H. M. AND WASHBURN, RICHARD N.

Gastric Secretion in Cases of Pernicious Anemia. Ann. Int. Med., 11:1834-1837, April, 1938.

Alsted has collected from the literature 32 cases of pernicious anemia in which hydrochloric acid was present in the gastric contents. However, many authors believe that achlorhydria is a constant finding in cases of pernicious anemia. The authors have reviewed the records of 906 consecutive cases from the files of the Mayo Clinic, in which a definite diagnosis of pernicious anemia was made. Achlorhydria was found in all the cases. This finding corresponds with the recent report of Sturgis on 600 cases of pernicious anemia. Hurst has observed four cases of pernicious anemia in which secretion of free hydrochloric acid returned following treatment of the gastritis. Achlorhydria was found in 34 of 36 cases in which analysis of the gastric contents was performed from two to twenty-one years prior to the onset of symptoms of pernicious anemia, while in two cases free hydrochloric acid could be demonstrated 19 and 17 years before symptoms of pernicious anemia developed. In only two cases was a hypochromic anemia found at the time of the original examination. The authors believe that pernicious anemia and simple achlorhydric anemia are separate clinical entities.

NIXON, EDWIN A.

Diverticulitis. Northwest Medicine, 37:97-100, April, 1938.

Diverticula and their sequelae are the commonest lesions to be found in the colon. Age and constipation cause these lesions to form through weakened musculature in the anti-mesenteric border of the colon and into the epiploic appendages. Roentgenologic examination by the combined barium enema and air injection offers greater opportunities for studying the numbers and location of the diverticula. Surgical treatment of diverticulitis consists in

individualizing the treatment of the complications.

Hanes M. Fowler, Fort Wayne.

COE, HERBERT E.

Imperforate Anus. Northwest Medicine, 37:97-97, April, 1938.

Methods of treatment for imperforate anus are outlined. Various procedures are described for use depending upon the local conditions found. Where the defect is due to a thin membrane occluding the anal opening and a sphincter is present the perineal approach is very satisfactory. In cases where the blind end of the bowel terminates some distance above the anal dimple a colostomy is advisable either as a temporary or permanent measure depending upon the possibility of later construction of an anal canal.

A case is reported which demonstrates most of the difficulties and complications which can occur during the treatment of this condition.

Hanes M. Fowler, Fort Wayne.

ATKINSON, ARTHUR J. AND IVY, ANDREW C.

Menstrual Edema. J. A. M. A., 106:515-517, Feb. 15, 1936.

Certain therapeutic procedures administered with the object of preventing menstrual edema failed with the exception of the administration of the gonadotropic principle from pregnancy urine, which was slightly effective, and emmenin (collip), which was markedly effective. The blood lipids, which varied considerably, were followed for more than ten months in one patient and were not significantly or strikingly influenced.

Hanes M. Fowler, Fort Wayne.

1938 GRADUATE FORTNIGHT OF THE NEW YORK ACADEMY OF MEDICINE

The Eleventh Annual Graduate Fortnight of The New York Academy of Medicine will be held from October 24 to November 4, 1938.

The subject of this year's Fortnight is DISEASES OF THE BLOOD AND BLOOD-FORMING ORGANS.

The Fortnight will present a carefully integrated program which will include clinics and clinical demonstrations at many of the hospitals of New York City, evening addresses, and appropriate exhibits.

The purpose of the Fortnight is to make a complete study and authoritative presentation of a subject of outstanding importance in the practice of medicine and surgery.

In the coming Fortnight, twenty-three hospitals have accepted the invitation to participate by having prepared afternoon clinics and clinical demonstrations which will be coordinated with the evening meetings. The

evening sessions at the Academy will be addressed by recognized authorities in their special fields, drawn from leading medical centers of the United States.

A comprehensive exhibit of books, pathological and research material, diagnosis, treatment and prevention whenever possible, clinical and laboratory diagnostic methods, X-rays, action of drugs and other therapeutic measures. Demonstrations will be held at regular intervals.

Among the main features to be pre-

sented at the meetings, in the clinics and in the exhibit will be:

Pernicious anemia
Other macrocytic anemias
Idiopathic hypochromic anemias
Other anemias benefited by iron therapy
Anemias of pregnancy
Aplastic and hemolytic anemias
The granulocytopenias
Formation and fate of the blood cells
The reticulo-endothelial system
Diagnostic significance of changes in erythrocytes

Diagnostic significance of changes in leucocytes

Infectious mononucleosis

The leukemias

Hodgkin's disease

Lymphomatoid diseases (other neoplastic diseases of the lymph nodes and bone marrow)

The polycythemias

Diseases of the blood in infancy and childhood

The blood clotting mechanism

The purpuras

The splenomegalies—their differential diagnosis—indications and results of splenectomy, etc.

Irradiation therapy in the blood diseases

The New York Academy of Medicine provides this program for the fundamental purpose of medical education. Consequently all members of the medical profession are eligible for registration.

The medical profession is invited to attend.

A complete program and registration blank may be secured by addressing Dr. Mahlon Ashford, The New York Academy of Medicine, 2 East 103d St., New York City.

The Spectre of Peptic Ulcer in HYPERCHLORHYDRIA

Excessive secretion of HCl frequently portends the development of peptic ulcer. Hyperchlorhydria, usually productive of pyrosis and epigastric discomfort, should be controlled not only to maintain the patient's comfort, but to lessen the probability of gastric or duodenal ulcer in the future.

Creamalin—the distinctive colloidal cream of aluminum hydroxide—offers exceptional advantages

for antacid therapy. It fixes 12 times its volume of N/10 HCl in less than 30 minutes. As it does not lead to a secondary rise in HCl secretion, to alkalosis, or to changes in plasma pH values, it may safely be given for prolonged periods. Creamalin, recognized for its dependable efficacy in peptic ulcer, not only relieves the pain of hyperchlorhydria promptly, but also stays or prevents the development of peptic ulcer.

Comprehensive literature sent on request.

PALMER, REX B.

Changes in the Liver in Amebic Dysentery With Special Reference to the Origin of Amebic Abscess.
Arch. Path., 24:3-327, March, 1938.

The author comments about the high incidence of liver abscesses in cases of amebic dysentery and the lack of specific information about the mechanism of their origin and development as noted in the literature. Craig collected 1529 cases of amebic dysentery which came to autopsy and found that abscess of the liver occurred in from 22 to 59 per cent in different series with an average of over 40 per cent. Councilman and Laffeur (1921) reported that 21 per cent of 1429 nonfatal cases had recognizable liver abscesses.

It has been believed that amoebae may reach the liver by one of three possible routes: 1. By direct extension through the bowel wall, the peritoneal cavity and the liver capsule. This method is supported by the presence of amoebae in the peritoneal cavity, by the rare occurrence of amebic abscesses of the abdominal wall secondary to amebic dysentery, and by the frequent location of the abscesses near the capsular surface of the right lobe of the liver. 2. By extension through the portal vein. Amoebae are frequently found in lumens of capillaries and venules near the intestinal lesions. 3. By extension through the lymphatics.

A Leader in Gastro-enterology Says . . .

"The recent advances in gastro-enterology have been of such magnitude and distinction that they engender in us a just pride and renew our determination to press forward toward our goal of perfection."

Dr. Ernest H. Gathler, Baltimore, Md., in his address at Kansas City before the section on gastro-enterology and proctology of the A.M.A.

The American Journal of Digestive Diseases

- ⑤ Now in its fourth year of publication—without alteration in its fixed principle of giving to the reading members of the medical profession the contributions of the best clinicians and investigators in the United States, Canada and Europe.
- ⑤ So formulated, and edited by one of the most capable and select editorial groups in contemporary medical journalism, the Journal has made unusual progress during the comparatively short period of publication . . . today, the editorial office is constantly in receipt of very valuable manuscripts which collectively form a cross section of new gastro-enterological thought.
- ⑤ The absence of "politics" from this set-up ensures to the reader an unbiased preliminary evaluation of submitted material by men pre-eminently qualified to judge the worth of MSS in the various sub-fields of this broad specialty.
- ⑤ Meeting the growing difficulty of prompt publication, the Journal is constantly diminishing its back log of material by insistence more and more, as time goes on, upon the idea of BREVITY in writing.
- ⑤ The American Journal of DIGESTIVE DISEASES is not only making friends but it is KEEPING friends. The renewal percentage each year and each month is a positive proof of the sound, month-by-month value of the publication, and it is recognized that this Journal provides today, as no other publication ever provided, a trustworthy postgraduate education in a field much more intricate and fascinating than has been generally supposed.
- ⑤ Once upon a time gastro-enterology was generally regarded as a specialty contaminated by faddism and quackery, but the pioneers, many of whom are still living and active on this editorial board have lifted it to the level of a strictly ethical study—and the Journal is playing an important role in facilitating this important branch of medical practice.

An Open Letter to the Physicians of North America

Do you realize that 60 per cent of all symptoms in general practice arise from the digestive tract?

Many diseases are intrinsic, and many at a distance reflect their symptomatology with great facility in the alimentary canal . . .

Is diagnosis of digestive diseases easy?

Apparently not. The old rule of thumb—"appendix, ulcer, or gall bladder" is no longer useful. We are becoming gradually acquainted with the disorders and diseases of the colon and reducing this information to some semblance of order. Physiology, bacteriology, chemistry, parasitology, clinical observation, animal experimentation, roentgenology, nutrition, allergy and psychology are the organized methods of approach to a fuller knowledge of

digestive diseases. And there still lies beyond, the dark continent of the small intestine, concerning which so little is positively known.

To the scholar, what is offered by this Journal is indispensable.

To the man too busy to indulge his yen for applied research, may we say this—an hour a month with the American Journal of DIGESTIVE DISEASES will provide the key to practical success in this most important, difficult, but "treatable" field.

Spend \$6.00 for a year or \$10.00 for 2 years NOW. Join the increasing group of doctors who enjoy this periodical. The card below is attached for your use, and is postage free.

A Valuable Therapeutic Aid

The judicious use of colon bacillus vaccine therapy in conjunction with the oral use of Soricin Tablets brings about a favorable response in many obstinate cases of chronic functional diarrhea, chronic headaches associated with chronic constipation or colon distress, chronic toxic vertigo and unstable colon.

B. Coli Vaccine-Detoxified (Merrell) is prepared from selected strains of *B. coli communis* (*Escherichia coli*) and *B. coli communior* (*Escherichia communior*) mixed in equal proportions and detoxified with Soricin (sodium ricinoleate).

B. Coli Vaccine-Detoxified (Merrell) is now available to physicians in the following strengths:

- 5 thousand organisms per cc.
- 50 thousand organisms per cc.
- 500 thousand organisms per cc.
- 5 million organisms per cc.
- 50 million organisms per cc.
- 250 million organisms per cc.
- 1000 million organisms per cc.

Physicians are invited to write for complete descriptive literature.

The Wm. S. Merrell Company
CINCINNATI, U. S. A.

This route is doubtful although amoebae have been found in the lymphatics of the colon.

The author reports in detail the gross and histologic changes found in the liver of one case of amoebic liver abscess coming to autopsy in his own service and in tabular form the important points in 18 additional cases of amoebic dysentery which came to autopsy in the services of the Cook County Hospital, the Alexian Brothers' Hospital and the Evanston Hospital during the years from 1929 to 1936.

In the case studied in detail the liver contained wedge shaped areas which resembled infarcts, and probably were, due to thrombosis of branches of the portal vein. In one instance an amoeba

was found in the thrombus. In these areas were small amoebic abscesses. The shape and distribution of the lesions gave the impression that the infection began in a branch of the portal vein and extended along its subdivisions toward the capsule and spread through the connective tissue of the triads into the parenchyma of the liver. It seemed probable that such an infarction due to intrahepatic portal thrombosis was an important factor in the production of the large amoebic abscess.

The periportal connective tissue was increased in 18 of the 19 cases. It was diffuse in some cases, patchy in others. The patchy fibrosis seemed to be healed small abscesses which represented foci in which amoebae had lodged. It seemed

probable that such small scattered abscesses might exist without the formation of large abscesses. The early abscesses begin as areas of lysis extending into the liver parenchyma from the portal triads, without little accompanying inflammatory reaction, and frequently increase in size by coalescing with other abscesses. The central area of liquefaction is bordered by a thin meshwork of fibrinous strands in which there are some lymphocytes and large mononuclear cells. Polymorphonuclear cells are seldom seen. The increase of the portal connective tissue tends to wall off the larger abscesses. This fibrosis also is often present in a diffuse and a focal manner of distribution without abscess formation. With this definite hepatitis there is likewise present degenerative changes in the liver cells—parenchymatous degeneration, fatty changes, hemosiderosis and lysis.

The author concludes that amoebae gain entrance to the liver by way of the portal vein. Abscesses originate in the portal triads.

In only 6 of the 19 cases was a diagnosis of amoebic dysentery made clinically.

N. W. Jones, Portland.

ROBINSON, SAMUEL C.

Exophthalmic Goiter and Gastro-duodenal Ulcer—Two Constitutionally Different Diseases. Illinois Med. Jour., 73:210-223, March, 1938.

Exophthalmic goiter and gastro-duodenal ulcer are shown to be psychogenic diseases yet different in their psyche and soma. The ulcer patient is long and thin. The hyperthyroid may be of any build but tends to be slender and underweight. The temperaments of the two types are contrasting. The goiter patient is fearful, excitable, anxious, juvenile, dependent and frigid, while the ulcer patient is worried, stubborn, inhibited, independent, conscientious, mature and heterosexual.

The two diseases seldom occur in the same individual. The value to be derived from the study of mutually antagonistic diseases is discussed. Pernicious anemia is shown to be a third psychogenic and contrasting disease seldom occurring with either of the other two. A theory of etiology of pernicious anemia is advanced.

Ten males to one female have ulcers while ten females to one male have exophthalmic goiter. The importance of sex predominance in any disease is discussed. The hyperthyroid patient has a rapid pulse, raised blood pressure, increased B.M.R., lowered blood cholesterol values. The ulcer patient has none of these. The goiter patient has lowered HCl values tending toward achlorhydria, enlarged and atonic stomach. The findings in the ulcer patient are the direct opposite. The

Buffer Alkalies Palatability Effervescence

Alka-Vess

A balanced formula of the buffer saline alkalies presented for the convenience of your patient in an accurate, quickly soluble, effervescent tablet.

When you consider alkalization to be an important adjunct to your regimen of treatment as for example in acute infections, fevers, urinary infections, allergic skin conditions, diarrheas, summer dehydration, may we suggest the superior pharmaceutical elegance and merit of Alka-Vess.

Each tablet contains calcium di-hydrogen phosphate 3 grs.; potassium bicarbonate 1 gr.; magnesium sulphate (dried) 1 gr.; sodium chloride 1 gr.; citric acid 19 grs.; sodium bicarbonate 31 grs.

In convenient tubes of 25 tablets

thyrotoxic patient has a thymico-lymphatic constitution indicative of a juvenile stage of development which is absent in the ulcer patient.

The symptoms, signs and laboratory findings of exophthalmic goiter are practically identical with those produced by overstimulation of the sympathetic division of the autonomic nervous system. The findings of gastro-duodenal ulcer are equivalent to those produced by overstimulation of the parasympathetic nervous system.

Hanes M. Fowler, Fort Wayne.

MEANS, J. H., HERTZ, S. AND LERMAN, J.

Nutritional Factors in Graves' Disease. Ann. Int. Med., Vol. 2, No. 2, pp. 429-437.

It has long been known that marked grades of malnutrition may result from thyrotoxicosis; and this in spite of increased food intake. Lately, however, attention has been called to the fact that malnutrition may cause or precipitate thyrotoxicosis. This was noted by one of the authors, especially in cases following a reduction program for

obesity. A study then by the authors of 35 cases confirmed this observation. In 14, the prethyrotoxic weight loss was occasioned by reduction cures, and the remainder by a variety of conditions such as the restricted diet in the treatment of ulcer, ulcerative colitis and diabetes. Thus may acute malnutrition be added to the better recognized factors which activate thyrotoxicosis.

The authors caution the physician and patient against too vigorous reduction cures for obesity. Also in the preparation of the thyrotoxic patient for operation, they urge that the possibility of nutritional disturbances be considered and if found, an attempt be made to correct them, in addition to the usual iodization.

The manifestation of nutritional disturbances found in the toxic patients, include, as well as general inanition, changes in musculature, skeleton, hematopoietic system, heart and psyche. The methods of correcting these defects include not only a high calorie diet for the general malnutrition but also one high in vitamins and minerals, as well. Vitamin B, in the form of Harris yeast tablets has been of particular value in increasing the appetite and benefiting the heart, in the authors' opinion.

The authors briefly cite several case histories illustrating some of the facts mentioned. In the reviewers' opinion this article is an important and timely one.

DOMBROWSKI, EDWARD F., GOLDSTEIN, H. H., BAY, A. P. AND EDLIN, J. V.
Induced Hyperinsulinism. Illinois Med. Jour., 73:147-151, Feb., 1938.

Patients given insulin shock therapy were studied to observe changes produced by induced hypoglycemia. It was noted that symptoms could be grouped under these five divisions: gustatory, vasomotor, neurologic and mental, cardiovascular, and temperature changes.

Gustatory manifestations were among the most frequent noticed, occurred early in the treatment, and consisted of actions indicating a desire for food, protruding and puckering of the mouth, smacking and sucking the lips, sialorrhea, and sucking of fingers, bedding, etc.

Vasomotor phenomena included perspiration and flushing, followed by pallor of the face and body and coldness of the extremities.

Neurologic manifestations noted were chiefly motor in character and included a variety of convulsive seizures, muscle spasms, and evidences of psychomotor restlessness. Hypotonia and diminished reflexes were a rather constant early feature.

The most striking cardiovascular change was an apparent right heart

MERCK & CO. INC. *Manufacturing Chemists* RAHWAY, N. J.

failure occurring a short time after the administration of glucose to terminate the coma.

All the patients showed some fall in body temperature and some showed marked lowering, even to below the lowest reading on the thermometer in spite of externally applied heat. Several of the cardiovascular collapses were noted at periods of lowest temperature. Temperature usually returned to normal within one to one and a half

hours after termination of the treatment.

The authors intend undertaking a more complete study of the separate groups of symptoms noted above.

Hanes M. Fowler, Fort Wayne, IVY, A. C.

An Outline of Liver Functions and Jaundice. Jour. Michigan State Med. Soc., 37:121-129, Feb., 1938.

Jaundice is a symptom of vital importance only when it is associated with

hepatic insufficiency. The seriousness of jaundice depends upon the extent to which the vital function of the liver is impaired or to the extent to which the cause of the jaundice may in time lead to hepatic insufficiency.

The functions of the liver are outlined as regards storage of food materials, manufacture of food materials and other substances, detoxication, blood volume regulation, excretion, and relation to the glands of internal secretion. Factors of safety and regeneration of liver cells and effects of extirpation of the liver are discussed.

White or lightly pigmented bile is found in cases of obstructed common bile duct or in severe toxic or infectious hepatitis. It is chiefly a secretion of the epithelium of the ducts and its presence there always denotes the presence of hepatic injury.

Jaundice is usually due to a disturbance either before the liver, in the liver, or after the liver. Each condition is discussed in detail.

The differential diagnosis of jaundice is discussed with reference to the various liver function tests such as galactose tolerance, hippuric acid test, bilirubin clearance, and bromsulphthalein clearance.

In obstructive jaundice the cause of death is unknown. It is probably due to hepatic insufficiency. A terminal renal insufficiency occurs. Physiologic disturbances seen are osteoporosis, hemorrhagic tendency, bradycardia and pruritis.

"Liver death" and "hepato-renal syndrome" are discussed with theories advanced as to causative mechanism.

In every biliary tract disease the factor of safety in the liver is impaired to a greater or lesser extent. Hence, much attention should be given to the proper preparation of the patient for operation and to the selection of the anesthetic.

The medical aspect of the treatment of jaundice is that for the treatment of hepatic insufficiency, namely, improve the detoxicatory and other functions of the liver. The following measures have been found useful, administration of glucose, calcium, and vitamins, blood transfusion, proper diet including glycine and chondroitin, and administration of bile salts.

Two pictures that state the case for KLIM in Ulcer Therapy

MILK CURD—Large, relatively indigestible lumps—presenting small combining surface to gastric juices

KLIM CURD—Small, friable particles—presenting a much larger combining surface to gastric juices.

AS a result of the drying process in manufacturing Klim powdered whole milk, the curd of Klim dilutions, following ingestion, precipitates in fine particles, which present a much greater combining surface to stomach acid.

In addition, an equivalent volume of Klim dilution provides 27% more protein for neutralization than the standard milk and cream mixture of the unmodified Sippy diet.

Clinical studies* show that the use of Klim in the Sippy therapy gives you simpler, more effective control of gastric acidity. It permits hourly feedings—14 a day instead of the usual 29. And your patients will appreciate the 40% lower cost of Klim dilutions.

Clip and send the coupon below for further information on Klim, and a complimentary supply for trial.

Some Nutritional Products of S. M. A. CORPORATION

SMACo NICOTINIC ACID (3-PYRIDINE CARBOXYLIC ACID)

Available in 20-milligram and 100-milligram tablets. Also crystals and ampoules. Trial bottles \$1.00. Council-Accepted for standardization and clinical experimentation without therapeutic claims at present.

SMACo CAROTENE-In-oil

For vitamin A activity, uncomplicated by other vitamins. Palatable—no unpleasant after-taste. Available in capsules and liquid.

SMACo CAROTENE-with-vitamin-D-concentrate-In-oil

For vitamin A and D activity together. Palatable. It combines the advantages of Carotene (Pro-vitamin A) with the vitamin D concentrate prepared from cod liver oil by the process developed at and controlled by Columbia University.

SMACo CAROTENE-and-vitamin-D-concentrate-In-COD-LIVER-OIL

For physicians who prefer to prescribe cod liver oil. Contains Carotene (Pro-vitamin A) and is fortified in respect to both vitamins A and D.

SMACo VITAMIN B₁ TABLETS (THIAMIN CHLORIDE)

In tablet form, each tablet containing 2 milligrams (200 units).

HYPO-ALLERGIC MILK

For milk allergy. Helps prevent eczema in patients hyper-sensitive to milk protein (Whole milk and skim milk).

ALERDEX

Protein-free Maltose and Dextrins. Helps to prevent eczema when used routinely due to absence of offending protein. Used with Hypo-Allergic Milk for infants.

PROTEIN S.M.A. (Acidulated)

A special food for prematures, whose nutritional requirements ordinarily include a higher protein and mineral intake than those of a full-term infant.

S.M.A.

The antirachitic and antispasmodic breast milk adaptation. For normal infants deprived of breast milk.

S. M. A. CORPORATION

continues to improve the quality of Mead's Brewers Yeast in the following respects, without increased cost to the patient:

1. Vitamin B potency raised to not less than 25 International units per gram. Also contains 42 Sherman vitamin G units per gram.
2. Bottles now packed in light-proof cartons, for better protection.
3. Improved bacteriologic control in harvesting and packing.
4. And NOW, since August 1, 1936, all bottles are packed in vacuum. This practically eliminates oxidation. Mead's Yeast stays fresh longer, as you can tell by its improved odor and flavor!

Mead's Brewers Yeast Tablets in bottles of 250 and 1,000.

Evansville, Ind.

U. S. A.

and small. In typical cases there is dysphagia, glossitis and atrophy of the tongue and the authors say they have never encountered these symptoms in chronic hemorrhagic anemia unassociated with deficient gastric secretion. They differentiate between chronic hemorrhagic anemia and this complex by these features: Koilonychia and paresthesias may be present without cord changes. In a case of a male with chronic hemorrhagic anemia they report the finger nails were thin, brittle and spoon-shaped and note that this state of the nails is not confined to cases of idiopathic hypochromic anemia. The writers questioned their patients carefully regarding menstrual blood loss and did not include those with excessive menstruation as instances of idiopathic hypochromic anemia. In discussing achlorhydria, the frequency with which it is associated with the so-called idiopathic hypochromic anemia, is noted and its possible deterring effect upon the absorption of iron is mentioned. Iron balance studies were made which showed that achlorhydria interferes with the absorption of iron. As dietary deficiency has been suggested as a cause of idiopathic hypochromic anemia the authors found a daily iron intake of from 4.14 to 6.74 mg. showed all of five patients studied to be in negative iron balance but when 4 of these subsequently received from 12.27 to 14.19 mg. of iron per day they were in a positive balance. "These results indicate that the requirements are above the figures given by Farrar and Goldhammer, and more nearly agree with Olson and Daum." No case of idiopathic hypochromic anemia was encountered which the authors considered was due to low dietary iron content alone. They think achlorhydria is more important than restriction of dietary iron intake in most cases. The writers state that there is a similarity between the idiopathic anemias associated with menstrual loss and that of pregnancy. "In one the iron is lost through menstruation, in the other through fetal requirements, and in both there is a deficient absorption of iron because of the achlorhydria." Speaking of iron metabolism the writers say: "It has been assumed that faulty metabolism of iron, aside from improper absorption, may be a causative factor in some cases of idiopathic hypochromic anemia. We have found no concrete evidence in the literature to support this hypothesis xxx."

Treatment: Strauss' dosages of commonly used iron preparations: Reduced iron 3 gm., ferrous carbonate 4 gm., iron and ammonium citrates 6 gm., ferrous sulphate 1 gm. A reticulocyte response may be expected and Heath regards a rise of 0.16 gm. of hemoglobin daily as a lower limit of a satisfactory response when the hemoglobin is below 7.8 gm. per 100 cc. of blood. The ad-

The
**KYMOGRAPH RECORDS
 ANTISPASMODIC ACTION**

of **TRASENTIN** "*Ciba*"

TRASENTIN. "*Ciba*" arms the physician with an antispasmodic of unusual value. It acts quickly to check all types of spasms of the hollow viscera. Exerting atropine-like relief in nerve fibre contractions. Trasentin is decidedly less toxic to the heart and pupil; it does not interfere with salivary flow. Controlling smooth muscle spasms like papavarine. Trasentin does not cause permanent suppression of contractions.

Trasentin is truly worthy of trial. You will appreciate its prompt efficiency, high tolerance and relative safety in—gastro-intestinal spasms (ulcer or subacute gastritis, cardio-spasm, pyloro-spasm, spastic obstipation), biliary tract spasms (as in gallstone colic), spasm of the urinary tract (incident to inflammation or calculi, tenesmus of the bladder), spastic dysmenorrhea.

Trasentin (hydrochloride of diphenylacetyldiethylaminoethanol) is available in Tablets and Ampules.

GASTRIC TISSUE JUICE EXTRACT

ENZYMOL

Proves of special service in the treatment of pus cases

ENZYMOL resolves necrotic tissue, exerts a reparative action, dissipates foul odors; a physiological, enzymic surface action. It does not invade healthy tissue; does not damage the skin.

It is made ready for use, simply by the addition of water. These are simply notes of clinical application during many years:

Abscess cavities	Carbuncle	After tooth extraction
Antrum operation	Rectal fistula	Cleansing mastoid
Sinus cases	Diabetic gangrene	Middle ear
Corneal ulcer	After removal of tonsils	Cervicitis

Originated and Made by

FAIRCHILD BROTHERS & FOSTER
NEW YORK

ministration of hydrochloric acid did not increase iron retention nor the rapidity of hemoglobin regeneration. Copper and a liver fraction have also been used with the iron. Regarding the use of iron parenterally the authors' conclusions agree with those of Brock who states that "there is never any indication for injections of iron in the treatment of anemia."

Summary:

1. Idiopathic hypochromic anemia, in most cases, is a chronic hemorrhagic anemia due to menstrual blood loss and an improper absorption of iron due to deficient gastric secretion. There is no evidence of faulty iron metabolism.

2. "Simple achlohydric anemia" is therefore a preferable term.

3. Massive doses of iron produce a more rapid hemoglobin response in hypochromic anemia than do smaller amounts, although 1 gm. and 3 gm. of iron and ammonium citrates per day produce a fairly satisfactory increase in some cases even though achlorhydria is present. These amounts lead to a storage of iron in addition to that used in hemoglobin formation.

4. Neither copper nor a liver fraction, when given in addition to the iron, increased the rapidity of hemoglobin production.

5. Iron, administered intramuscularly in a tolerated dose, did not produce a hemoglobin response."

A Teaspoonful Makes A Tumblerful Of "Jelly"

Burton, Parsons & Co.

(Established 1885)

Washington, D. C.

MATHIS, JOHN A.

Enteritis. Illinois Med. Jour., 73:325-327, April, 1938.

The etiology of chronic enteritis is outlined as follows:

Mechanical: as by irritating foods. Chemical: (a) hematogenous, as by mercury, (b) direct, by drugs and cathartics. Bacterial: (a) specific, as typhoid bacillus, (b) non-specific, as occurs in achylia, duodenitis, etc.

The most valuable symptoms and findings are: colicky pain after meals radiating to the left hypochondrium of relatively short duration and not relieved by alkalies, a feeling of "unquietness" in the abdomen, and an indescribable feeling of nervousness after food which may be accompanied by sweating, hot flashes, vertigo, feelings of extreme weakness, or even fainting. The most important objective symptom is a tender area about half way between the umbilicus and the left costal margin. X-rays reveal a rapid gastric emptying and hyper-peristalsis of the small bowel. The stool examination is of the utmost importance, in fact, the diagnosis is established on the basis of the fecal content.

The treatment is chiefly dietetic and should be based upon the smooth diet as suggested by Alvarez. If constipation is troublesome, milk, Betalactose, or fruit juices may be used. Mineral

Normal children frequently complain of fatigue. Careful study reveals that they do not consume enough food to provide them with necessary energy requirements, half of which are derived from carbohydrate.

The energy supply should be in the form which is easily digested, not readily fermented and which does not affect the appetite for other foods. Karo meets all these requirements.

Infant feeding practice is primarily the concern of the physician, therefore, Karo for infant feeding is advertised to the Medical Profession exclusively.

FREE to Physicians only:

Convenient Calculator of Infant Feeding Formula: accurate, instructive, helpful. On receipt of Physician's prescription blank, giving name and address, the Calculator will be forwarded. Write Corn Products Sales Co., Dept. D N-6, 17 Battery Place, New York, N. Y.

oil may be needed, especially if astringent drugs are prescribed. Treatment must be adhered to for several months after the cessation of all symptoms.

Hanes M. Fowler, Fort Wayne.

PROGRAM

Preventive medicine will be the keynote of the 23rd annual meeting of the American Association of Industrial Physicians and Surgeons which will be held concurrently with the Midwest conference on Occupational Diseases at the Palmer House in Chicago, June 6th, 7th, 8th and 9th, 1938.

Dr. Edward C. Holmblad, 28 E. Jackson Blvd., Chicago, Chairman of the Program Committee, announces the most interesting program in the history of this organization.

Advance programs of the meeting are available to any doctor interested and will be sent without charge to any practicing physician interested in attending this meeting. The sessions will be open to any practicing physician in accordance with the educational program of the Association to spread the propaganda of preventive medicine and absenteeism of employees.

The very constructive work being conducted by the American Association of Industrial Physicians & Surgeons to co-operate with general practitioners and specialists in not permitting the

practice of industrial medicine to interfere with medicine and surgery in general practice is a refreshing thought to everyone in the medical field and this meeting of the Association at the Palmer House should be productive of great good.

For an advance copy of the program or for information on exhibits, address —Mr. A. G. Park, 540 No. Michigan Avenue, Chicago.

BEST, R. R. AND HICHEN, N. F.

Non-operative Management of Remaining Common Duct Stones.
J. A. M. A., 110:1257, April 16, 1938.

During the past few years the authors have been doing delayed cholangiograms on all cases of common duct drainage or biliary fistula. These have revealed the presence of stones or foreign bodies such as blood clots in ducts which were explored by palpation, probing, scopings, irrigation and suction at the time of operation. Therefore, cognizant of the high mortality attending secondary attacks on the biliary tract, they attempted to dislodge these foreign bodies by various non-operative measures.

The following method has been used, and is extended over a three day period.

On the first 1/100 grain of glyceryl trinitrate is placed under the tongue three times; on the second day atropine, grains 1/100 is given orally or hypodermically three times; on the third day the glyceryl trinitrate is repeated. Each morning the patient is given two drachms or more of magnesium sulfate in warm water and one ounce of olive oil or thick cream is given at bedtime. The common duct is irrigated daily through the T tube, catheter or fistula with normal saline. After this, 10 to 30 cc. of warm, sterile olive oil or lipoiodine is placed in the tube and left there if the patient does not complain of pain. Decholin or proeholen, tablets 3 or 4, are also given four times daily. This routine may be repeated as many times as necessary with several days rest between times. The method is usually contraindicated in complete obstruction because of the danger of hastening liver destruction, and it should never be used in those cases in which jaundice is present.

Francis D. Murphy, Milwaukee.

HARTSOCK, CHARLES L.

Differential Diagnosis of Jaundice.
Cleveland Clinic Quarterly, 5:102-107, April, 1938.

By the use of the van den Bergh reaction, jaundice may be separated into two types, namely, hyperbilirubinemia

Prompt Relief—Rapid Healing in

PEPTIC ULCER

LACTALUMINA

The original colloidal aluminum hydroxide for therapeutic use

Literature and sample on request

**CROOKES
LABORATORIES, INC.**
NEW YORK, N. Y.

LACTALUMINA reduces the irritation produced by excessive acidity in peptic ulcer by its effective "buffering" action. Pain and other clinical symptoms are rapidly relieved, promoting prompt healing without danger of alkalosis, kidney damage or secondary rebound of acidity . . . For use orally or by the "continuous drip" method.

Supplied in 8 oz., 16 oz., 80 oz. and 1 gallon bottles.

In intestinal toxemia, KAO-LACTOS E, an effective combination of Crookes Colloidal Kaolin, Lactose and Vitamin E, aids in controlling putrefaction and inducing a healthy gastro-intestinal tract . . . Supplied in powder form in 4 oz. bottles . . . Sample on request.

Therapeutic Preparations for the Medical Profession

BASIC OPERATIONS IN COMMERCIAL CANNING PROCEDURES

IV. SEALING THE TIN CONTAINER

BRIEFLY, the method of food preservation commonly known as "canning" involves subjecting food in a permanently sealed container to a heat process. The heat process destroys spoilage organisms present on the raw food material; the seal on the container prevents reinfection of the food by such organisms. It is, therefore, obvious that the sealing operation—"closing" or "double-seaming" as it is known in the industry—is one of the most important in the canning procedure.

The manufacture of tinplate and "sanitary" cans is described elsewhere (1).

The open cans are received at the cannery in paper cartons or in washed paper-lined box cars, together with the covers which are contained in fiber shipping tubes. Figure 1 shows a can and end ready for use.

In modern canning practice, the cans are first conveyed by automatic runways to can washers, and thence to the filling tables or fillers where the correct amount of properly prepared raw food is put into the cans. The covers or "ends" are placed in the automatic sealing or "closing" machine to which the open can containing the food is mechanically conveyed. In this machine the ends are "double-seamed" onto the can. This operation is portrayed by the accompanying cross-sectional pictures.

In Figure 2 is shown the relation of can to cover before the sealing operation is started; note the relative position of the "curl" on the cover and the "flange" on the can. In this curl, the can manufacturer has placed a gasket or "compound," usually containing rubber. Figure 3 is a series of photographs illustrating the sealing operation in which the curl and flange are first rolled into position and then the layers of metal flattened together to form the final "double-seam" in Figure 4. The rubber compound originally present on the cover supplies the binding material between the layers of metal necessary to insure a permanent or hermetic seal on the container. Figure 5 illustrates in cross-section a closed sanitary can as it comes to the consumer.

In the past twenty-five years great progress has been made in the development of tinplate, compounds and automatic sealing machines. Collectively, these developments enable present-day canners to impose a permanent seal on the cans containing their products more easily and rapidly than ever before in the history of canning.

DUOCHOL
(PLESSNER)

in Chronic Cholecystitis Toxic Hepatitis Stone-Free Cholangitis

Duochol (Plessner) provides the specific pharmacologic influence needed in many affections of the biliary passages. Containing highly purified bile salts and sodium salicylate (2 gr. of each), it intensifies bile secretion by the liver and increases cholecystic evacuation. Drainage of the bile ducts and gallbladder is thus encouraged, leading to rapid subjective and objective improvement in chronic cholecystitis, toxic hepatitis, and stone-free cholangitis.

Buffered Neutral Antacid

Tri-Calsate neutralizes gastric HCl yet causes no relief in acidity or alkalization of stomach contents. No gas, no constipating, palatable, economical. Proved by nine years' clinical use. Write for trial package and literature.

F. H. PAXTON & SONS, INC.
457 E. Ohio Street Chicago, Ill.

TRI-CALSAATE

due to increased production, and hyperbilirubinemia due to decreased excretion. The first type must be due to some disease that increases the destruction of red blood cells, while the second type must be due to factors affecting the liver or bile ducts, thus interfering with the excretion of the normal production of bilirubin. So-called hematomogenous jaundice, such as is produced by hemolytic blood dyscrasias, hemolytic fevers and certain drugs is easily recognized as such, and the exact cause can usually be determined by appropriate studies.

The real problem in the differential diagnosis of jaundice is presented in those cases due to disease of the biliary system. Three types of biliary tract disease should be differentiated:

1. Cellular damage to the liver. Catarrhal jaundice or Weil's disease, acute yellow atrophy, toxic hepatitis, etc.
2. Diffuse intrahepatic biliary obstruction. The cirrhoses, finely infiltrating malignancies, etc.
3. Extrahepatic obstruction of the large duct. Gall stones, pressure on duct from tumors, etc.

In differentiating between these types of jaundice reliance must be put chiefly upon clinical findings. The galactose tolerance test is one test, however, that yields valuable information if done in cases of early jaundice. This test affords a means of separating off the group due to damaged liver cells in which it is so important that no operation be performed.

Much better diagnostic methods are to be desired to distinguish between the pure obstructive type that is so frequently amenable to surgery and the hepato-obstructive type in which surgery only shortens the patient's lives. At present, however, exploration must be utilized until better methods are discovered.

Hanes M. Fowler, Fort Wayne.

BEST, W. H.

Epidemic Diarrhea of the Newborn. J. A. M. A., 110:1155, April 9, 1938.

This is the study of twenty-seven outbreaks of diarrhea in the newborn which have occurred in the New York City Hospital over the period from July, 1934, to December, 1937. The disease is characterized by the sudden onset of driness in a healthy infant followed within a few hours by loose, watery, yellowish stools containing no mucus or blood. Vomiting and distention may be present. Marked dehydration occurs and death may occur early or late in the disease. It appears to be a disease of infants under four weeks of age and in no instance has it been communicated to adults. It is very contagious and the incubation period usually is short. The outbreaks were

controlled only by closing the maternity service and renovating the nurseries.

The etiologic agent has not been established. Bacteriological examination of the stools has revealed a variety of different organisms in each outbreak. Virus studies also have revealed nothing. The author believes that the cause may be some organism pathogenic for young infants only.

The disease is controlled by isolation, closing of the maternity services until all contacts have been discharged and thorough cleansing of the nurseries. Prevention may be brought about by having everything that comes in contact with the infant's nose or mouth in a surgically aseptic condition.

Francis D. Murphy, Milwaukee.

KESTEL, J. L.

Hypertrophic Pyloric Stenosis in Adults. Jour. Iowa State Med. Soc., 28:147-148, April, 1938.

The author concludes that hypertrophic pyloric stenosis with a moderate degree of obstruction is probably more common than it is generally believed to be. It can be recognized radiologically. Three cases are reported illustrating various degrees of obstruction and retention produced by the pyloric hypertrophy.

Hanes M. Fowler, Fort Wayne.

TRI-COSTIVIN

CLINICAL NOTES

by KNOX

*(One of a Series of Correspondence Exchanges
with Physicians about Knox Gelatine.)*

QUERY: A doctor writes, "In your literature touching on the use of Glycine (amino-acetic acid) in gelatine for the dystrophies, I suggest that you add Postural or Orthostatic Hypotension for two reasons, first, you will be doing a favor to the medical profession by calling to their attention this disease, and secondly, offering a cheaper manner of obtaining glycine. I am enclosing a letter from a Mrs. — who maintained a systolic blood pressure of 120 when recumbent, but upon standing, it fell so rapidly that she could not get across the room without fainting. All of her symptoms and physical signs were those of Orthostatic Hypotension for which ephedrine hydrochloride had little or no effect, but with the addition of glyceroll, or glycine, 30 grams daily, she has slowly improved and is able to walk for some distance. I would appreciate it if you would send her a menu in which she can get 10 or 15 grams daily of glycine."

ANSWER: Dear Doctor: Thank you indeed for your interesting suggestion. We can add nothing to your noteworthy observation other than to bring it to the attention of the medical profession as widely as possible.

Probably one of the best means of obtaining a concentrated gelatine ration is the following recipe.

"The KNOX FRUIT STIR"

Place the contents of 2 envelopes of Knox Gelatine in an ordinary sauce or cereal dish. Add 8 table-spoonfuls of any desired fresh or canned fruit juice, such as grape juice. Let soak for five minutes and eat with tea-spoon.

Total: 4 ounce mixture—100 calories

Why you should insist on Knox Sparkling Gelatine

Because Knox Gelatine is 85% protein in an easily digestible form—because it contains absolutely no sugar or other substances to cause gas or fermentation, Knox Gelatine should not be confused with factory-flavored, sugar-laden dessert powders. Knox is 100% pure U.S.P. gelatine. Knox Gelatine has been successfully used in the dietary of convalescents, anorexic, tubercular, diabetic, colitic, and aged patients.

Sample and useful Dietary Booklets on request. Write Dept. 475

KNOX SPARKLING GELATINE
IS PURE GELATINE—NO SUGAR

KNOX GELATINE LABORATORIES

Johnstown, N. Y.

FOR the medical management of gastric and duodenal ulcers, Colloidal Aluminum Hydroxide has proved strikingly effective . . . (1) As a protective mechanical barrier against irritation; (2) by its astringent action in helping to control hematemesis; and most important, (3) by its high acid-combining powers, by which it fixes free acid and prevents digestion of the delicate fibrin of the clot by strong unbuffered gastric juice. The healing

process is thus facilitated, without disturbance of the acid-base balance, or evolution of gas, or stimulation of a secondary acid rise. To provide a product meeting the most rigorous standards of quality, Colloidal Aluminum Hydroxide (Truesdale), manufactured by special process, has been released to the medical profession, as an efficient, highly palatable and thoroughly ethical preparation. By direct titration, using Toepfer's reagent as indicator, it can adsorb and neutralize at least 12 times its volume of N/10 hydrochloric acid in less than 30 minutes.

The excellent clinical results attained both by its oral administration, and by the use of the newly improved Truesdale Drip Apparatus, recommend it for the gastroenterologist's use.

Available in 12 oz. bottles.

A Comparison of Streptococci from the Colon with Barger's Organism*

By

JOHN F. KESSEL, Ph.D.

INTRODUCTION

IN the routine culture of fecal material from stools and of scrapings from proctoscopic examinations one encounters numerous Gram positive cocci which have been variously described by different authors as Micrococci, Enterococci, Diplococci or Streptococci. These, for the most part, are diplococci in form and tend to grow in short chains. No marked differences appear between strains, either in morphology, colony formation or action on blood agar plates although attempts have been made by some writers to differentiate them by such criteria.

Eseherich (1886) gave the name *Micrococcus ovalis* to a streptococcus recovered from the stools of children. In 1897 Hirsch and Libman introduced the term

belonging to his alpha type and by fermentation reactions shows sixty-four combinations possible within this alpha type.

Dible (1921) in studying 134 strains of fecal streptococci found that certain of his organisms fermented mannitol while others did not, that they seldom fermented raffinose, and that they were unusually resistant to heat. By his methods they neither produced hemolysis nor formed methemoglobin. He attributes little significance to these organisms as pathogens. He inclines to the view that the term *Enterococcus* should be accepted for the group as a whole since *Streptococcus faecalis*, as described by Andrewes and Horder is limited to mannitol fermenting types and therefore, would exclude many non-mannitol fermenting types.

TABLE I

Fermentation reactions of strains of streptococcus recovered from the colon

Streptococcus enteritis, while in 1899 Thiercelin described in detail a streptococcus from the human stool which he called *Enterococcus*.

Andrewes and Horder (1906) gave the name *Streptococcus faecalis* to a streptococcus from the intestine which they considered occasionally to be pathogenic. The strains with which they worked fermented mannitol, lactose, salicin and sucrose and certain subsequent workers have endeavored to limit the name *Str. faecalis* to those forms from the intestine which ferment these substances.

Besson (1913) accepts the name *Enterococcus* for the common streptococcus of the intestine and considers the same to be a facultative parasite. He is of the opinion that it is widely distributed throughout the body, occurring in the naso-pharyngeal region as well as the alimentary tract. He does not describe its reaction on blood but from the acute condition described as being caused by certain of his organisms it would seem likely that he observed hemolytic streptococci as well as methemoglobin-producing types.

Brown (1919) in his Table 11 lists *Str. faecalis* as

Bagger (1926) isolated ninety-two strains of a streptococcus from cases of peritonitis and fifty-eight strains from the normal intestine. These he designated as *Enterococcus*. His strains all fermented glucose, galactose, maltose, lactose, salicin and mannitol. He differentiated ten types on the basis of biochemic reactions and found them to be pathogenic for rabbits only occasionally. They were somewhat variable in their heat resistance qualities and no mention is made of their reaction on blood. He concluded that agglutination is usually only strain specific and therefore useless for classification.

Barger (1930) and Rankin, Barger and Buie (1932) report a streptococcus isolated from ulcerative colitis lesions which they describe as a diplo-streptococcus. Barger endeavors to differentiate his organism from both *Enterococcus* and *Str. faecalis*, mainly because it does not ferment mannitol, ferments raffinose, is less heat resistant and does not grow well on plain agar. His organism produces methemoglobin on blood agar and by his methods is usually pathogenic for rabbits.

Torrey and Montu (1934) observed the usual differences in heat resistance and in carbohydrate fermentation among their strains isolated from the intestine and conclude that no correlation is apparent

*From the Department of Bacteriology, School of Medicine, University of Southern California and the Los Angeles County Hospital, Los Angeles.
Submitted November 4, 1937.

between fermentative activity, resistance to heat, other biologic characteristics and serologic relationships.

Since it is apparent that the exact status of *Streptococcus faecalis* and of *Enterococcus* is uncertain and since one in laboratory diagnostic work is often required to pass judgment upon the significance of a streptococcus isolated from the human colon a study was begun in which a comparison was made between a number of strains of such Streptococci, both from normal individuals and from patients who exhibited pathology of the colon in an attempt to determine the biochemic and serologic types present and also to ascertain whether any one type is more closely associated with colitis symptoms than others. With the courtesy of Dr. Bergen it has also been possible to compare several strains of his organism with the streptococci isolated in this study.

METHODS AND OBSERVATIONS

Isolation

In the current study, material procured at proctoscopic examination or from feces, was first planted in carbonated veal infusion broth, pH 7.6, which after 12-18 hours of incubation was streaked on blood agar plates. Colonies were picked from the plates and transferred to mannitol, salicin, lactose, saccharose, raffinose, glucose, aesculin and inulin for strain identification. Most strains were positive in glucose and aesculin and negative in inulin. Therefore these three carbohydrates are not included in Table I. It was usually possible to isolate several different strains of streptococci from each patient by this method and these fall into three different species, *Str. faecalis*, *Str. mitis* and *Str. salivarius*, as classified by Andrewes and Herder, if only mannitol and salicin are considered as differentiating carbohydrates. By the use of three other carbohydrates i.e., lactose, saccharose and raffinose, in which marked variation is shown, each of these

species may be divided into several strains as shown in Table I.

Only ten different fermentative strains as based on the above reactions actually have been recognized to date. Although these ten strains are the same as those most commonly encountered by previous observers they are not thought to be exhaustive and it is probable that additional ones will be encountered.

Fermentation Reactions

Whether this multiplicity of strains is due to their instability of fermentation, or whether there actually are numerous stabilized types of fecal streptococci based on fermentation reactions may still be questioned. Most writers, however, have been inclined to credit their strains with fermentative stability. Among such was Welch (1929), who recognized six different strains.

In the present study relative constancy of fermentation reactions is recognized since eight of the species isolated have been tested frequently in this laboratory over periods varying from one to three years and have remained constant with the exception of one strain of *Str. faecalis*, IV which lost its mannitol fermenting power. A few strains, however, kept for shorter periods of time, illustrated a fermentative variability when first isolated.

It is difficult to compare absolutely the strain relationships of organisms studied by previous workers since identical carbohydrate substances have not been used by all. Brown (1919) in summarizing the work of several previous workers compares the action of alpha streptococci in mannitol, lactose, salicin, raffinose, inulin and saccharose and shows sixty-four possibilities. He suggests a very comprehensive numbering system using units 1 to 8 and decimals 0.1 to 0.8 for the sixty-four strains. *Str. mitis* becomes a1.1, *Str. salivarius* a2.1 and *Str. faecalis* a5.1.

In comparing our ten strains recovered from the

human intestine with his numbering system, the following relationships are found to exist:

<i>Str. faecalis</i> , I	α5.2
II	α5.1
IV	α5.5
VI	α7.1
<i>Str. mitis</i> , I	α1.2 (Bargen's original organism)
II	α1.1
IV	α2.5
<i>Str. salivarius</i> , I	α2.2
II	α2.1
VIII	α4.5

Of the non-inulin fermenting strains, it will be observed that for the most part, our isolations are identical with the strains most commonly listed in his table. It is, therefore, apparent that certain similar strains of streptococci of the alpha type are recovered most commonly from the human intestine, both by previous observers and in the present study.

Dible (1921) after an exhaustive comparison of 270 strains, divides his organisms into four fermentative groups:

- I A mannitol-fermenting group
- II A raffinose-inulin fermenting group
- III A "Combined" group which splits mannitol as well as raffinose
- IV An undifferentiated group which lacks action on any of these three carbohydrates.

Bagger (1926) working only with mannitol fermenting strains procures ten major groups, most of which have several sub-groups. He uses thirty-two different fermentative substances for comparison. It is obvious that the greater the number of carbohydrates used, the greater will be the number of strains differentiated.

The ten strains found in this study were compared with the following strains of Bargen's organism:

Bargen A	Received from Dr. Bargen in September, 1930.
Bargen B	Received from Dr. P. W. Brown, February, 1933, from an ulcerative colitis patient from whom I had originally isolated the same fermentative species of organism in Los Angeles.
Bargen C	Received from Biologic Firm C
Bargen D	Received from Biologic Firm D.
Bargen E	

Bargen A and Bargen E gave the sugar reactions described by Bargen (1930) as being characteristic of his organism and are identical with Brown's α1.2, and our *Str. mitis*, I. Bargen B, isolated both in this laboratory and in Dr. Bargen's laboratory from the same patient corresponds with our *Str. mitis*, II and to Brown's α1.1. Bargen C corresponds with our *Str. faecalis*, II. Brown's α5.1 and is also identical with the *Str. faecalis* of Andrewes and Worder. Bargen D corresponds with Brown's α5.5 and with our *Str. faecalis*, IV. It is a close variant of our *Str. faecalis*, II differing only in saccharose fermentation.

METHEMOGLOBIN FORMATION

Observers are not agreed in their conclusions concerning the formation of methemoglobin by *Str. faecalis*. Brown (1919) places *Str. faecalis* in the

alpha type and Orcutt (1926) working with the enterococci of calves records the production of green zones on blood agar plates. On the other hand Dible (1921) using Blake's method of testing for methemoglobin reports negative results. Bargen considers that his organism produces methemoglobin. Other writers, for the most part, have neglected statements on this point.

Recent text books also vary in their accounts concerning the reaction of *Str. faecalis* on blood agar plates. Topley and Wilson (1936) state that most strains produce no change in blood agar medium while Zinsser, Bayne-Jones (1934) describe it as belonging to the alpha type. They further state that *Str. faecalis* is probably the same organism which Bargen has associated with ulcerative colitis.

It is a well known fact that the kind of blood used in making tests for the presence of methemoglobin and the type of plate used, whether streak plate or pour plate may be responsible for a variation in results, e.g., a strain of *Str. viridans* will produce a more definite green coloration when sheep blood or horse blood is used than when rabbit blood is used. The appearance on human blood is intermediate between sheep blood and rabbit blood. It is also true that methemoglobin formation is more easily detectable in a pour plate where the colonies are well spaced than in a streak plate.

In this study as shown in Table II a comparison was made between (1) a streak plate and a pour plate, using rabbit blood, (2) pour plates, using rabbit blood and sheep blood and (3) Blake's Horse Serum Method, using both rabbit cells and sheep cells.

It will be seen that the results were somewhat in doubt with certain of the strains when streaked on plates prepared from rabbit blood. In pour plates the methemoglobin formation was more apparent and when sheep cells were used the green coloration was apparent with all strains. With Blake's Horse Serum Method, methemoglobin was formed both in the presence of rabbit cells and sheep cells, though it was de-

tectable in larger amounts when sheep cells were used.

Three representative strains used in this study were sent to Dr. J. H. Brown with the request that he check their methemoglobin production. He kindly did so and in personal communication reports as follows: "In human blood agar all three strains showed slight greenish discoloration about the deep colonies with little or no hemolysis. I regard them as of a weak alpha type although in some media they might appear as gamma type. I have tried to retain the terms alpha, beta and gamma as descriptive terms of appearances in blood agar rather than as names of types of streptococci and I see no objection to describing a streptococcus as producing the alpha appearance in one medium and the gamma appearance in another. In my experience this may be the case with *Str. faecalis* but most strains can be made to produce alpha zones in suitable blood agar."

It is thus observed that the strains of streptococci recovered from the human intestine in this study possess a tendency to produce methemoglobin, although the amount may be somewhat variable, dependent upon the method used for testing. The strains of Bergen's organism observed by comparison also produced methemoglobin but to no greater degree than the strains of fecal streptococci herein described.

DISTRIBUTION OF STRAINS

In this study streptococci have been isolated by culturing smears or scrapings taken by proctoscopic examination from 85 patients showing symptoms clinically designated as ulcerative colitis and from 107 other patients showing no subjective colitis symptoms. The distribution of strains most commonly recovered is shown in Table III. It will thus be seen (1) that the strain representing the original *Streptococcus faecalis* of Andrews and Horder, i.e. our *Str. faecalis* II is the one most frequently recovered both from normal individuals and from patients with colitis, (2) that by the method employed in this study no one strain, even *Str. mitis* I, which corresponds to Bergen's original description is encountered more frequently from patients with colitis than from normal individuals.

Attempts to associate organisms showing lactose or non-lactose fermenting characteristics, mannitol or non-mannitol fermenting characteristics or organisms showing other individual fermentation reactions with a higher percentage of patients exhibiting colitis symptoms than with normal individuals failed.

Heat Resistance

Unusual heat resistance is one of the characteristics of fecal streptococci reported by Dible (1921). He used the ability of streptococci from the intestine as contrasted with other streptococci to survive heating at 60° C. for 30 minutes as a standard. Bergen in 1930 mentions the heat resistance of *Str. faecalis* in contrast to his organism which is less heat resistant.

Rafsky and Manheims (1932) emphasize the heat resistance test as a point of differentiation between Bergen's organism and other fecal streptococci, stating that the *Enterococcus* is viable after heating for one hour at 60° C. while Bergen's strain is killed by such an exposure.

In the thermal death point tests made in this study twenty-four hour broth cultures of the strains to be tested were placed in capillary tubes about four inches

long and the ends sealed. These were placed in a water bath heated to 60° C. One tube was removed in five minutes, one in thirty minutes and one at the end of an hour. There was growth in all tubes removed at the end of five minutes. The results of the thirty and sixty minute tests are shown in Table IV.

It will be observed that of the seventeen individual cultures tested belonging to our ten strains, all with the exception of *Str. faecalis* I resisted the temperature for thirty minutes. Ten of the strains resisted the temperature for one hour. Even certain strains which give the same fermentative reactions as *Str. mitis* and as *Str. salivarius* resisted the 60° C. temperature for thirty minutes. The strains of Bergen's organism tested all survived 60° C. for thirty minutes and three survived a temperature of 60° C. for one hour.

Injection into Rabbits

Although most workers assign a pathogenic role to intestinal streptococci when injected into mice, reports of their pathogenicity in rabbits are variable. Macé (1912) considered them slightly pathogenic, Besson (1913) records intestinal lesions and Bagger (1926) reports moderate pathology. Dible (1921) on the other hand does not consider them pathogenic for rabbits. Bergen (1930 and later) reports intestinal pathology in a relative high percentage of rabbits given intravenous inoculations of his strain of streptococcus.

In this study two rabbits have been inoculated intravenously with each of the various strains of streptococci considered. Two cubic centimeters of a twenty-four hour broth culture from each of the strains here reported and of Bergen A, B, C, D and E were injected into the ear vein of the rabbits. In no case was any diarrhea noted during a period of two weeks and autopsy at the end of that time showed no intestinal lesions to be apparent though necrotic areas were present in the cortex of kidneys inoculated with *Str. faecalis* II and IV, *Str. mitis* I, II and IV and with *Str. salivarius* II and VIII and Bergen A. Culture of these

foci demonstrated in each case the same type of streptococcus that was originally inoculated.

Agglutination Tests

Streptococci from eight of the strains were employed in the agglutination studies as shown in Table V. Antisera were prepared from each strain by intravenous injection first of killed antigen and later of the living antigen into rabbits.

The following observations may be made from a

study of the table: (1) Within certain strains, e.g. *Str. faecalis* II the strain antiserum agglutinated more strains of the same fermentative type (to a titre of 160 or above) than were agglutinated by the antiserum of other strains. (2) This did not obtain for all strains, however, e.g., *Str. mitis* II antigens showed a greater degree of agglutination with the antiserum of both *Str. faecalis* VI and *Str. mitis* I than with antiserum of *Str. mitis* II. One must therefore conclude

that a comparison of fermentation reactions with agglutination tests does not indicate a degree of agglutination within individual fermentative strains that can be considered highly specific. (3) If an attempt is made to group all the strains of *Str. faecalis* together, of *Str. mitis* together and of *Str. salivarius* together it will be seen that the number of positive agglutinations to a titre of 160 or above is greater within each species group than within either of the other two species groups, e.g., there are 25 agglutinations of *Str. faecalis* antigens by *Str. faecalis* antisera while only 18 *Str. faecalis* antigens were agglutinated by *Str. mitis* antisera. Likewise there were 25 agglutinations of *Str. mitis* antigens by *Str. mitis* antisera and only 14 agglutinations of *Str. mitis* antigens by *Str. faecalis* antisera. While these results indicate a slightly closer serologic relationship of the strains within each of the three species here listed it is not as exact as the serologic differences which exist between most species of bacteria and would therefore be of little value in classification.

These results agree in general with those of Bagger (1926) and of Torrey and Montu (1934) who obtained inconsistent serologic results between strains of intestinal streptococci.

DISCUSSION

I. Comparison of Intestinal Types and Upper Alimentary Tract Types.

No satisfactory agreement has ever been reached as to what actually constitutes the intestinal streptococci nor absolute criteria established as to how they may be differentiated from other streptococci. Should all common streptococci recovered from the colon or its contents be regarded as intestinal varieties or should some be considered as throat and pharynx types, that have progressed to the colon? Short chained streptococci from both regions appear to possess similar capacity in the production of methemoglobin. In this study at least all streptococci, which according to the fermentation reactions, might be designated either as *Str. faecalis*, *Str. mitis* or *Str. salivarius*, possess a similar degree of heat resistance.

Gordon (1905) was the first who attempted to differentiate the mouth types from the intestinal types. He compared his series of streptococci recovered from saliva with Houston's series of fecal streptococci. None of his strains found in saliva ferment mannitol and few of them salicin while all the Houston's strains from the feces ferment salicin and certain of them mannitol. A comparison of their most common types with strains recovered in this study will be of interest.

Gordon's second, third and fourth types in order of frequency of occurrence when reduced to fermentative reactions comparable with ours correspond to *Str. salivarius* of Andrewes and Horder, our *Str. salivarius* II. Thomson (1927) in discussing *Str. salivarius* states that many of Gordon's salivary types and of Houston's fecal types are closely related to *Str. salivarius* and that its variants pass by gradations into *Str. faecalis* from which form he is unable to draw any absolute distinction.

It is noteworthy, however, that Gordon's tables show this type (i.e. *Str. salivarius*) and its raffinose fermenting variant, our *Str. salivarius* I, to occur many times more frequently in the saliva than any other type and that these types are rare in Houston's, in Dible's and in our series of intestinal streptococci.

The type occurring next in frequency in Gordon's salivary types possesses the same fermentation reactions as *Str. mitis* I and Bagen A of this study.

Among Houston's strains from the intestine the first two in order of frequency have the same fermentation reactions as *Str. mitis* (Andrewes and Horder), our *Str. mitis* II or Bagen B of this study. *Str. mitis* I or Bagen A just mentioned above is a closely related form varying only in raffinose fermentation. Dible (1921) in his Table I lists 142 strains, fifty of which are either our *Str. mitis* I or II. Thomson (1927) in discussing *Str. mitis* states that this form is essentially saprophytic, occurring chiefly in human saliva or feces.

The variety occurring third in frequency in Houston's intestinal types and most commonly in this study corresponds to *Str. faecalis* (Andrewes and Horder), our *Str. faecalis* II or Bagen C of this study. It is also the most common type recorded in Dible's Table I. This type was not reported in Gordon's salivary series.

Judging from these comparisons one would conclude: (1) The type of streptococcus known as *Str. salivarius* is the form encountered most commonly in the mouth, the same being found less frequently in the intestinal contents. (2) The types known as *Str. mitis* and *Str. faecalis* are encountered more frequently from the intestine.

The question arises as to the justification for regarding these three as separate species and one can not answer this with certainty until a criterion for species differentiation is established for streptococci.

If one could correlate fermentation relationships with agglutination types or with some other serologic identity with as great constancy as one does in certain other groups of bacteria, e.g., the typhoid-dysentery group, the problem would be simple. Since no one type appears to be more pathogenic than another, one must select either fermentation reactions or serologic relationships as an initial basis for comparison. For present comparison, fermentation reactions are emphasized since most workers have selected these in the past and since no evidence has been presented to demonstrate the presence of stable serologic types.

II. Name for Intestinal Types.

Several names for the streptococci from the intestine are encountered in the literature, the three most common being *Streptococcus enteritis* Hirsch and Libman (1897), *Enterococcus* by Thiercelin (1899), and *Streptococcus faecalis* Andrewes and Horder (1906). The original description given to the last species limited the same to mannitol, lactose, salicin and saccharose fermentation types while no similar specific biochemic limitations have been assigned to *Str. enteritis* or to *Enterococcus*. Since the organisms in question are morphologically streptococci, they should all be assigned to the genus *Streptococcus* which has the priority over *Enterococcus*. The word *enterococcus* is nothing more than a descriptive term, indicating the region of the body in which the organisms are commonly encountered and should not be used to designate a genus. The species name *enteritis* would indicate an organism causing an acute inflammatory condition and for this reason does not convey the correct impression of the relationship of the streptococci under discussion. Fortunately the term is not commonly used in recent literature and since the descrip-

tion originally applied to this organism indicates a mixture of α and β types this name should not be retained.

If Brown's suggestions are accepted that the reactions of streptococci in media containing blood are variable and that the terms α , β and γ should be used as descriptive terms only, then *Str. viridans* should not be retained as a species name for this group.

One is left then to consider two main possibilities: (1) Accept the species name *Str. faecalis* and enlarge its definition to include not only mannitol fermenting types but non-mannitol fermenting types of short chained, heat resistant methemoglobin producing streptococci. (2) Accept the three species names *Str. faecalis*, *Str. mitis* and *Str. salivarius* as given by Andrewes and Horder (1906) and differentiate the same in a manner similar to that indicated in Table I, or in Brown's Table II allowing for several fermentative strains within species.

For the time being the second alternative would present the fewest difficulties and is therefore used in this study as a simple method of procedure, each species being further subdivided into strains as shown in Table I. Agglutination studies already summarized also tend somewhat to substantiate this division, although they are not regarded as being actually specific.

Brown (1919) Table II, has already suggested a practical method for divisional grouping of streptococci. His arrangement of the carbohydrates, however, in so far as the alpha strains are concerned seems somewhat unfortunate since one of the first practical divisions of these streptococci would seem to be on the basis of inulin fermentation which would separate the pneumococcic types from the more common streptococcic varieties.

Most intestinal strains fail to ferment inulin and the arrangement of these non-inulin fermenting strains in Table I is suggested as a means of simple grouping. On the basis of mannitol and salicin fermentation it is possible to differentiate the three species *Str. faecalis*, *Str. mitis* and *Str. salivarius*, names already encountered in the literature. On the basis of their additional reactions in lactose, saccharose and raffinose, eight fermentative strains are possible within each species. In practice, all these have not been encountered; the ten strains here recorded being the ones most commonly found in this study and by previous workers. They may, therefore, be expected to be the ones most frequently encountered in the future.

III. Relation of Bargaen's Organism to These Species.

Bargaen (1930) described his organism as follows: "The diplococcus ferments dextrose, lactose, saccharose, maltose, raffinose and salicin, but usually not mannite." Since then he apparently has enlarged the scope of his organism to include other fermentative types which correspond to several of the other fecal types compared in this study. Five of his strains which were compared in this study gave fermentation reactions, one each corresponding with our *Str. faecalis*

II and IV and with *Str. mitis* II and two with *Str. mitis* I, the last being identical with his original description. Five other strains of Bargaen's organism described by Torrey and Montu (1936) fall into two different groups, J. B. being *Str. faecalis* I and L.S., W.M., O.J.T. and H.D. being *Str. salivarius* I.

There would therefore, appear to be no merit in attempting to differentiate the streptococcus which of late has come to be known as Bargaen's organism or the "diplo-streptococcus" of Bargaen from other common streptococci of the intestinal tract.

In this study autogenous antigens prepared from the ten specific strains collected from colitis patients have been used both as antigens for intradermal tests and as bacterins for therapeutic purposes, both in conjunction with and without Bargaen's commercial antisera. Intradermal tests on patients with ulcerative colitis have shown positive reactions with antigens other than the Bargaen A organism just as frequently as they have with antigens prepared from *Str. mitis* I or from Bargaen A organism.

SUMMARY

1. Streptococci isolated from stools and from proctoscopic scrapings of patients exhibiting symptoms of colitis and of individuals with no colitis symptoms have been compared with five strains of streptococci commonly designated as Bargaen's "diplo-streptococcus."

2. The streptococci observed have fallen into ten different fermentative strains when grown in media containing inulin, mannitol, salicin, lactose, saccharose and raffinose, respectively.

3. Representatives of all the strains compared in this study have produced methemoglobin on blood agar plates, have resisted a temperature of 60° C. for thirty minutes, and have exhibited similar morphologic and cultural characteristics. None has produced intestinal lesions when injected intravenously into rabbits, though kidney lesions have been a common result of such injections.

4. By the use of mannitol and salicin only, it is possible to refer each of these ten strains to one of the following species of Andrewes and Horder: *Str. faecalis*, *Str. mitis* or *Str. salivarius*. By the additional use of lactose, saccharose or raffinose, several strains of each species have been recognized.

5. Agglutination reactions do not correlate to any appreciable degree with the ten fermentative strains listed. A closer relationship exists, however, when all strains which give the fermentation reactions of *Str. faecalis*, *Str. mitis* and *Str. salivarius* respectively are grouped together.

6. No one strain has been associated more frequently with ulcerative colitis patients than with non-colitis patients.

7. Of the five strains of Bargaen's organism compared, one was identical with our *Str. faecalis* II which is also identical with *Str. faecalis* of Andrewes and Horder; one with *Str. faecalis* IV which is a variant of *Str. faecalis*; one is identical with *Str. mitis* of

Andrewes and Horder, our *Str. mitis* II; one with our *Str. mitis* IV and two with our *Str. mitis* I. Borgen's strains in our hands did not exhibit any apparent differences from our strains in (1) the action on blood plates, (2) heat resistance qualities or (3) pathogenicity in rabbits.

8. There would, therefore, appear to be no reason

to regard the streptococci described as Borgen's diplo-streptococcus as being essentially different from other types of alpha streptococci commonly recovered from the human alimentary tract and his strains may belong to the species *Streptococcus faecalis*, *Str. mitis* or to *Str. salivarius*.

IV. An Experimental Study of the Hydrogen-Ion Concentration and Chemistry of Bile, its Effect Upon Stones, and a Suggestion as to Therapeutic Application of Ox-Bile in Gall Bladder Disease*

By

SAMUEL MORRISON, MAURICE FELDMAN,

JOHN C. KRANTZ, Jr.

and

FRANCES F. BECK
BALTIMORE, MARYLAND

THERE are many factors to be considered in the etiology of gall stones. Although much has been written regarding the formation of stones there are but few significant contributions on this subject. It is noteworthy that but little investigative data exist on the hydrogen-ion concentration of bile and many of these have been obtained from fistulous bile in both humans and animals. As to the relation between the hydrogen-ion concentration of bile and the formation of gall stones, the literature is especially scant.

pH DETERMINATIONS IN NORMAL ANIMALS AND MAN

Hydrogen-ion determinations by the electrometric method were made of the gall bladder bile from the guinea pig, dog, rabbit and the human. The pH in a series of 26 normal guinea pigs averaged 8.9. In the normal dog the pH of a series averaged 6.2. The rabbit gall bladder bile was 8.8; cat 5.3 (Okada); ox 7.5 (Okada). The normal human gall bladder bile ranged between 7.0 and 7.5. These findings indicate that the hydrogen-ion concentration of bile varies in different

species and demonstrates that in the herbivorous animal the bile is normally alkaline while in the carnivorous animal the bile is more likely to be acid. On the other hand, in the human subject, an omnivorous species the hydrogen-ion concentration of gall bladder bile is close to the neutral point.

THE EFFECT OF DOG'S BILE ON STONES IN VIVO

In a previous study (1) the authors confirmed the findings of others (2), that gall stones of the cholesterol type placed in the dog's gall bladder would dissolve. Numerous explanations have been advanced to account for this phenomenon, but none seems to be entirely satisfactory. A constant finding in the dog's gall bladder bile is its acidity which possibly may be one of the factors concerned with its capacity to dissolve stones. It occurred to us that since in the dog there was apparently a relationship between the pH of bile and the dissolution of gall stones it would be desirable to select an animal with an alkaline gall bladder bile in order to determine its effect upon similar gall stones. The guinea pig was selected for these experiments. We were able to demonstrate that gall stones placed in the guinea pig's gall bladder were not affected by the

Submitted November 5, 1937.

alkaline bile. Furthermore, it was also noted that no change occurred in the pH of bile owing to the presence of stones.

COMPARATIVE STUDIES OF NORMAL BILE AND FISTULOUS BILE IN RELATION TO THEIR EFFECTS UPON GALL STONES AND HYDROGEN-ION CONCENTRATIONS

As it has been shown that human gall stones will dissolve in normal dog's acidic bile and will not dissolve in the normal alkaline bile of the guinea pig it seemed important to determine what effect a dog's alkaline bile would have on the dissolution of human stones.

In a previous communication (3) we have shown that the normal dog's acidic bile could be made alkaline by the production of a fistula which prevents concentration of the bile by the gall bladder. These studies demonstrated that when gall stones were implanted into the gall bladder through the fistulous opening, the dissolving effect of the bile was lessened, and in fact in some instances there was actually an increase in weight of the stones. These observations seem to indicate that alkaline bile may have some tendency to favor the formation of stones but this has not as yet been definitely proved.

It is interesting in this connection to point out that Neilson and Meyer (4) observed that in gall bladders of various laboratory animals injured by infection the pH of the bile remains constantly identical with that of the secretion derived from the liver owing to the inability of the gall bladder to bring about its usual change in the bile.

EFFORTS TO CHANGE THE pH OF BILE BY FEEDING OF VARIOUS SUBSTANCES

(a). CHEMICALS

Gall bladder bile possesses a high buffer capacity and it is difficult to alter its hydrogen-ion concentration. This applies also to the concentrations of its various constituents. The feeding of various chemical

substances to animals has little tendency to change the hydrogen-ion concentration of gall bladder bile. Even drugs known to be excreted partially by the liver such as salicylic acid showed no influence upon the pH of gall bladder bile. Ottenheimer and Kahn (5) found that the oral administration of sodium citrate, sodium bicarbonate or hydrochloric acid failed to cause any significant alteration in the pH of bile. They also noted that solutions of phenoltetrachlorophthalein and phenoltetraiodophthalein when injected intravenously in animals seemed to be excreted in a colloidal state and have no effect on the reaction of bile.

(b). FOODS

Since the chemicals employed had little effect upon the pH of bile it occurred to us that feeding experiments might change the pH. Three normal dogs were placed upon a vegetable diet consisting of lettuce, carrots, cabbage, etc. After a period of 18 days the bile was obtained directly from the gall bladder and hydrogen-ion determinations made. The following pH values were obtained in the three animals—6.92, 6.29 and 6.26—which indicates that the feeding of vegetable diet to dogs had no significant effect on the pH of the bile. In another experiment four guinea pigs were fed a meat diet in order to determine whether their alkaline bile could be made acidic by this change of diet. After a feeding period of 14 days the following pH determinations were obtained—8.74, 8.63, 8.86, 8.64. These are essentially normal values for the guinea pig, and thus it is readily seen that the change from a herbivorous to a carnivorous diet produces no significant change in the pH of bile in these normal animals.

Bronner (6) in 1933 studied cholecystectomized human subjects with a tube in the ductus choledochus and observed that by varying the diet he was able to shift the pH of the bile to the alkaline side with a vegetable diet and to the acid side with a meat diet. Bronner believes that variations in the pH and changes that occur concomitant with it are important factors

TABLE I

14	6.65	17	6.48	42	59	1.818	0.105	1.713	94

in the origin of stones. Notwithstanding Bronner's observations on the effect of food upon fistulous bile in the human subject it is our opinion that these changes actually occur in liver bile and not in normal gall

The pH of this bile was determined immediately with a glass electrode. Following ox-bile feedings the pH values approximate those of liver bile. The results are recorded in Table I.

TABLE II

Effect of ox-bile on bile pH and stone weight in dogs. 0.6 grams daily by mouth

Dog	Before Implantation of Stone	After Implantation of Stone	Total Days Fed	Weight of Stone in Grams		Weight Loss Grams	Weight Loss %
	pH	pH		Implanted	Recovered		
1	6.48	None	42	0.793	None		
2	None	6.07	77

4	7.75	6.61	62	1.713	0.692	1.621	95
5	6.68	6.41	82	1.952	1.600	0.352 (calc.)	18
6	6.68	6.21	77	1.135	0.443	0.695	61

bladder bile. Our experience, at least in the normal dog and guinea pig, does not confirm Bronner's findings in the fistulous human subject.

(c). VITAMINS

In a previous communication (1) we reported, as the result of our experiments, that the feeding of vitamins A, B-complex and D had no significant effect upon the formation or dissolution of gall stones in the dog.

(d). OX-BILE

Since few drugs are known to effect the hydrogen-ion concentration of bile we decided to use powdered Extract Ox-Bile, U. S. P. as an oral medication. Fourteen dogs were utilized in this experiment. Two tablespoonfuls (8 grams) of ox-bile were mixed with the dog's rations and fed over a period of weeks. Interesting results were obtained from these experiments. It was found, for instance, by feeding large amounts of ox-bile that the dog's normally acidic bile could be changed to alkaline. No untoward effects developed from this dosage of bile.

Following the oral administration of ox-bile it was observed that the gall bladders were considerably distended. The bile was obtained aseptically by hypodermic needle puncture. Its color was altered from the normal dark brown to a striking deep olive green.

THE EFFECT OF FEEDING OX-BILE AFTER IMPLANTATION OF GALL STONES INTO THE GALL BLADDER

In 14 animals which had previously been fed daily with 8 grams of ox-bile, a cholesterol gall stone was placed in each gall bladder to determine the effect of this alkaline gall bladder bile upon the stones. After a varying period of time (see Table I) it was observed that a marked diminution in the size of the gall stones took place. It seemed therefore that the hydrogen-ion concentration of the bile was not the sole factor in the dissolution of gall stones as was suggested in our previous investigations (3, 7). However, chemical analysis of these biles resulting from the feeding of ox-bile disclosed a decrease in bile acids and a diminution of protein. The diminished amount of protein resulting from dilution binding less of the normally occurring cations of bile, may account in part for the alkalinity.

THE EFFECT OF FEEDING SMALL AMOUNTS OF OX-BILE

Inasmuch as large doses of ox-bile changed the pH of dog's acidic bile to alkaline it was of interest to determine whether a similar response followed small doses, approximating the normal human dosage. Six dogs were observed in this experiment. Two, ten grain capsules of ox-bile daily were administered orally to each dog. It is noteworthy that in these experiments the pH of the dog's gall bladder bile did not change

TABLE III

Effect of Keto bile acid on bile pH and stone weight in dogs. 0.7 grams daily by mouth

Dog	Before Implantation of Stone		After Implantation of Stone		Total Days Fed	Weight of Stone Implanted	Weight of Stone Recovered	Weight Loss Grams	Weight Loss %
	pH	Days Fed	pH	Days Fed					
1	7.61	28	6.11	37	65	1.410	0.674	0.756	54
2	6.62	47	6.17	38	81	1.244	0.752	0.462	36
3	6.62	27	7.21	37	65	1.028	0.507	0.591	58
4	7.61	27	6.17	37	65	1.612	0.493	0.579	36
5	6.75	28	7.30	37	65	1.252	0.746	0.666	53

following the administration of such small doses. These experiments would indicate that to obtain results in gall bladder disease larger doses would be required in order to influence the composition of bile and thereby probably obtain better therapeutic results (see Table II).

CHEMICAL STUDIES

Chemical studies have been made of the gall bladder bile following the feeding of bile salts. Our results are summarized in Table IV. It is interesting to note in studying this table that the effect of feeding large

THE EFFECT OF FEEDING MIXED KETO BILE ACIDS

Five dogs were observed in this experiment. To each animal 3, 3 $\frac{3}{4}$ grain tablets* were administered daily by mouth. The results indicate that on the whole the feeding of keto acids in small dosage did not materially change the pH of bile. It would seem at least from these few experiments, that the dissolution of stones was less than was found in the control or after the feeding of ox-bile. (see Table III).

TABLE V
pH of human bile

18	"	7.60
19	Pancreatitis	7.18

doses of ox-bile is to dilute the various constituents of the normal dog's bile. This is associated with an increase in the pH. On the other hand, small doses of ox-bile have been found to be ineffective in changing the chemical proportions of the various constituents nor do they change the hydrogen-ion concentration. These experiments suggest that feeding of ox-bile in small doses as is ordinarily administered in the human subject, is therapeutically ineffectual.

Following the feeding of keto bile acids it is of interest to note that although there was considerable dilution of the chemical constituents of the bile the pH was not significantly altered. By comparing the effect of ox-bile with keto bile acids it is readily observed that the ox-bile in large quantity appears to have a greater diluting effect.

HUMAN BILE

As the result of our studies on animals, we became interested in the hydrogen-ion concentration of gall bladder bile in human cases of pathological and normal gall bladders. Biles were obtained at operation from gall stone cases and hydrogen-ion concentrations were determined on the fresh bile. Strikingly enough, it was noted that in each case of gall stones which we examined, the hydrogen-ion concentration of the bile proved to be alkaline. These studies corroborate the data already obtained in our animal experimentation. In 15 human subjects possessing gall stones the hydrogen-ion concentration determinations obtained are higher than normal. (See Table V). We have also found that the type of stone did not significantly influence the pH in these human cases. The results of other pathological conditions are also recorded in this Table.

CONCLUSIONS

1. In a study of gall bladder bile of different species one of the most striking features is the apparent immutability of its characteristic hydrogen-ion concentration.

2. The pH of bile does not readily change following various forms of therapy.

3. It is our belief that various foods do not significantly alter the pH of gall bladder bile.

*This material was kindly supplied to us by G. D. Searle & Co., Chicago, Illinois.

4. The feeding of large doses of powdered extract ox-bile U. S. P. changes the dog's normal acidic bile to alkaline and also dilutes the chemical constituents. Feeding of smaller doses does not change the pH of gall bladder bile in the dog nor does it have any diluting effect.

5. The feeding of keto bile acids (0.7 gram per day) did not change the pH of gall bladder bile in the dog nor did it bring about as great a dissolution of the stones as is noted in the normal and ox-bile fed animal. This dosage of keto bile acids approximated

the human dose. The diluting effect was much less marked than in feeding large doses of ox-bile.

6. The pH of bile is not the sole criterion in the dissolution of gall stones, as is demonstrated by the fact that even though large doses of ox-bile change the pH of dog's acidic gall bladder bile to the alkaline side, they do not significantly influence the degree of dissolution of implanted human cholesterol stones. In our opinion, the dissolution of the stones by the alkaline bile after the feeding of large quantities of ox-bile, is due to its chologogue effect.

The Effect of Estrogenic Hormone on Gastric Acidity**

By

LEON SCHIFF, M.D.

and

HENRY FELSON, M.D.

With the technical assistance of

JANE GRAFF, B.A.

and

BETTY MEYER, M.A.

THE well known fact that the modal gastric acidity in man is higher than in woman, and conversely the greater frequency of anaecidity in the female (Bloomfield), suggests a possible relationship between sex hormones and gastric secretion. The effect of "Theelin" on gastric acidity has been studied in the dog by Winkelstein, who observed no constant change.

As we were unaware of any similar observations made in man or woman, it was decided to administer Theelin to a group of human subjects. We were particularly interested to see whether or not achlorhydria could be produced.

METHOD USED

A group of twenty individuals was selected, consisting of twelve males and eight females (including six castrates). The ages varied between 23 and 75 years with an average age of 42 years. The patients were ambulatory and reported to the laboratory in a fasting state. They were instructed not to swallow any saliva.

A Rchfuss tube was introduced into the stomach and the fasting contents were withdrawn. One-half mg. of histamine phosphate‡ was given subcutaneously and continuous aspiration carried out in 10 minute periods for a total of one hour. The presence of bile and mucus was recorded.

Prior to the institution of treatment, two or more gastric analyses were done at intervals of 5 to 10 days. During treatment the analyses were continued at intervals of one to two weeks and after treatment at intervals of about two weeks.

The patients were arbitrarily divided into three groups. The first group was composed of nine men who were given relatively large doses of "Theelin" over a short period of time. The group was restricted to men because of their tolerance for larger individual doses of the hormone (Table I). The doses ranged from 4,000 to 20,000 International Units per injection, the usual dose being 10,000 units. The average duration of treatment was 27 days; the average number of injections, 21, and the average duration of study, 9 months (Table 1).

The second group, composed of four women (3 castrates) and three men, received smaller doses of

Fig. 1

the hormone over relatively longer periods. The doses ranged from an initial injection of 500 units to one of 4,000 units, with an average of approximately 3,000 units. The average duration of treatment was 108 days; the average number of injections, 61, and the average duration of study, 5 months (Table II).

The last group, composed of five women (3 castrates) received smaller individual doses of "Theelin," but over relatively shorter periods. The doses ranged from 500 to 6,000 units with an average of 2,930 units. The average duration of treatment was 35 days, the average number of injections, 20 and the average duration of study, 7 months (Table III).

A total of 308 gastric analyses was made. The determination of average acidity before and after treatment showed no change in 11 cases, an average increase of 20 or more in maximum acidity in 3, and a decrease of 20 or more in 6 (Table IV). As we have seen even greater changes in acidity following histamine injection occur spontaneously in a trained subject, we are not inclined to attach any significance to such variations. A composite curve made of all the analyses in all the patients (excepting the 15 analyses in the patient with achlorhydria) shows very little variation, although there is a suggestion of a slight decrease in acidity following treatment (Fig. 1).

Of four males with loss of libido prior to treatment, two showed no improvement with reference to this complaint; whereas the other two showed definite improvement during treatment and for some months later. Of two castrates with diminution of potentia

TABLE IV
Effect of Theelin on average maximum free acidity

		No Effect	Rise*	Fall*
Group I	Cases with normal acidity	5	1-(24)	1-(26)
	Cases with increased acidity	1		
	Cases with achlorhydria	1		
Group II	Cases with normal acidity	1		2-(21) 2-(88)
	Cases with increased acidity			2-(55) 2-(25)
	Cases with decreased acidity	2		
Group III	Cases with normal acidity	1	1-(21)	1-(59)
	Cases with decreased acidity	1	1-(21)	

*A rise or fall is indicated by an increase or decrease of 20 or more in the average maximum free acidity, the exact change being included parenthetically.

following recent oophorectomy, one noticed increase of sexual desire whereas the other noticed progressive decrease in spite of treatment. Hot flashes, present in several instances disappeared under treatment.

SUMMARY

The intramuscular administration of Theelin in either relatively large (approximately 10,000 units) or smaller doses (approximately 3,000 units) over periods varying from 15 to 167 days, has no effect on the gastric acidity of man within a total observation period of 2 to 13 months. (Composite curves of acidity suggest a questionable decrease following such treatment).

Migraine; Epilepsy: Their Association with Hypothyroidism*

By

A. I. RUBENSTONE, M.D.†

PHILADELPHIA, PENNSYLVANIA

THIS report is prompted by the coincident finding of hypothyroidism in a woman and her two daughters. The mother had a history of severe intractable migraine since adolescence, which in early middle life was accompanied by epileptic seizures, and both daughters' early adolescences also were attended by severe and frequent attacks of migraine.

This familial occurrence is not unusual, since hereditary transmission of migraine is unquestioned, and even though Moebius' figure of 90% may be high, certainly Timme's estimate of 50% is conservative, with a far higher maternal than paternal transmission.

The symptom complex of migraine has been the plague of the human race and theory upon theory has been advanced for its causation. We are still confronted by its puzzling etiology—sphinx-like, mute, stubborn and refractory to treatment; often impossible to eradicate. This is not surprising, for migraine, though it may last for many years, has not to date revealed itself in any definite resultant structural change.

The indefinite underlying pathology of this affliction together with its tendency often to disappear spontaneously in later life, allowed a wide theoretical speculative field as to etiology, and can account for the many theories and explanations of the clinical phenomena. Undoubtedly the primary anlage in the hereditary transmission, is an underlying cellular, molecular weakness or an allergy, superimposed on which are the many elements that make for a disturbance in bodily equilibrium.

These elements either singly or in combination, are the exciting causes of the recurrent outbreaks; especially—physical and mental fatigue, disturbance of the special senses, toxic absorption and endocrine dysfunction.

Of all the theories propounded as causative in migraine, in the light of our present day knowledge of functional pathology, the most plausible are allergy and endocrine dysfunction. One is impressed with the striking coincidence of migraine and manifestations of allergy, found, compared with the control group, four times as frequently in the families of patients suffering from migraine. One is also impressed with the basic similarity and behaviorism of migraine to such diseases as asthma, hay fever, urticaria, eczema and serum sensitivity.

The recurrent migrainous explosion, with intervening relatively normal periods, is suggestive of a cumulative effect in its production that could easily fit in with the changing ebb and tide of inter-related function of the secretory glands. The frequency of attacks at the end of menstruation, and the complete disappearance of attacks during pregnancy, are more than coincidentally related to pituitary and ovarian

function. It is also more than coincidence that the migrainous symptoms can be produced by the administration of Follutein; also the frequency of low thyroïdal function present in migraine. Especially noteworthy is the very favorable response of post menstrual and hypothyroid migraine to specific glandular therapy.

In a review of the literature on both migraine and epilepsy, in which basal metabolic rates were estimated, there is preponderance of low readings—both in men and women, especially in the latter.

In the studies reported by Balyeat, Moehlig, Low and Krema, and N. C. Stevens, the preponderance of low basal rates obtained are significant in emphasizing the frequency of hypothyroidism in this disease. Confirmatory also is the increased cholesterol content of the blood, found by Mason and Moehlig. Low and Krema contend that thyroid gland dysfunction or hypofunction may be the basis for the migraine and the prime cause of the allergic manifestations. Also significant, is Stevens' explanation of the production of toxemia in migraine, which likewise places the responsibility on lowered thyroid function. He states—"The hormone of the thyroid gland which regulates metabolism of the body is intimately connected with the nervous, circulatory and digestive systems. If there is an insufficient amount of hormone, the bodily processes are slackened, mentality is sluggish, the pulse is slowed and desire for food diminished. The possibility exists that even the food consumed, is incompletely burned, that the poisonous products of incomplete combustion accumulate in the system, until the limit of tolerance is reached and then an attack precipitated. The toxin then may act anaphylactically or allergically; the thyroid then may undergo a temporary stimulation and for a short time secrete more than its ordinary amount of hormone.

The bodily processes are thus stimulated, with consequent elimination of toxin and with a quick return of the organism to normalcy. This may account for the patient's feeling of well being immediately following the attack, and also for the temporary higher basal metabolic readings. When the thyroid relapses to its former condition of low output, the cycle begins again, to culminate in another periodic explosion."

"A. R.," housewife, age 50, first came under 'my' observation in 1925, with a history of attacks of migraine at 4 to 8 week intervals. These attacks, later increasing in severity and frequency with no apparent relation to menstrual periods which were regular and painless. Past medical history, beyond measles and an occasional head cold, was negative, and the familial background was surprisingly free of migraine and epilepsy. She married at 22—her husband coming from a migrainous family. In the succeeding eleven years, there were born four healthy children; no abortions. There was relative freedom from attacks during pregnancy. At about 38 years of age, the attacks of migraine (previously ushered in by nausea

*From the Department of Medicine, Mount Sinai Hospital.
†Attending Physician, Mt. Sinai Hospital, Philadelphia, Pa.
Submitted December 3, 1937.

and vomiting, vertigo, scintillating scotomata and blurring of vision, followed by severe left temporal and frontal headache) were sometimes replaced by attacks of grand mal with aura of some duration, consisting of nausea and vertigo, and followed by unconsciousness with tonic and clonic spasms.

She had repeatedly, during the preceding 16 years, received the whole gamut of studies, including X-rays of the skull, sinuses, biliary and gastro-intestinal tracts, blood chemistry, cytology, serology, spinal fluid examination and tests for allergy—all with negative results. In addition to symptomatic sedative drugs, many suspicious teeth had been extracted, nasal sinuses intensively treated and eyes frequently re-fracted.

When the patient came under my observation in 1925, examination revealed an intelligent and mentally alert woman of 40. In addition to her persistent attacks of migraine occasionally replaced by epileptic attacks, there were complaints of feeling cold, of abnormal fatigue, of a tendency to moderate constipation, but menstruation was regular and normal. Physical examination, aside from a pair of diseased tonsils and a cardiac rate of 65, B.P. 140/90, was essentially negative.

She submitted to another recheck of all previous studies, also with negative results; and, in addition a basal metabolism reading showed a plus 4% (in retrospect it is noteworthy that this reading was done two days after an attack of epilepsy). A tonsillectomy, elimination diets for minor allergic sensitivity, also colonic irrigations which were popular at the time, were effected—all had but little influence on her attacks. In 1929, on a regular visit to the office, she was in the prodromal state of nausea, and with the mental sluggishness usually preceding an attack. I was struck by an unusual bradycardia—so I ordered a recheck on her basal metabolism, the following morning, which read minus 25%. Thyroid in one grain doses three times a day, retained with difficulty because of nausea, modified and shortened the attack that immediately followed. There was no recurrence of either migraine or epilepsy from 1929 to 1932—during which time her basal metabolic rates were maintained within normal range by from one to one and a half grains of thyroid extract a day.

The patient was not seen during the greater part of 1932. Early in 1933, following an attack of epilepsy, she again came, admitted that over confident, she had not taken thyroid extract for the preceding four months—basal rate then was minus 16%. From that time she has regularly taken one to one and a half grains of thyroid extract a day and her basal rates have varied between minus 8% and plus 5%. Her last basal metabolism reading was minus 1% and her blood cholesterol 184, and she has been well.

Of the four children, the oldest—a girl of 25, and the youngest—a boy of 17, have so far escaped. The second and third children—two girls, both developed migraine.

The older of the two, "J. R." was not suspected of migraine until 1931 because no headache accompanied periodic attacks of nausea, vomiting and epigastric

pain, present since early childhood. One of these episodes in 1928 was followed by dizziness and a mild catarrhal jaundice. All the thorough studies were negative, and no noticeable improvement occurred following removal of tonsils and nasal sinus treatment, together with elimination diets and symptomatic measures. In 1931, at the age of 18, for the first time, severe headaches accompanied these abdominal upsets. Basal metabolism readings at this time were minus 14% and minus 17%, cholesterol 163. Her response to thyroid therapy was as dramatic as her mother's; since then she has been free of both abdominal and cephalic attacks; has completed a college course, is now teaching and entirely well.

In 1932, the younger sister "L." a bright girl of 16, developed typical attacks of migraine similar to her mother's. The outstanding abnormality on complete study was a minus 18% basal metabolism, with a cholesterol of 210. For the past three years, she has been on thyroid therapy, with no return of symptoms, until last September 18th, when mild headache and nausea recurred—persisting for three days before she returned for examination, when her basal metabolic rate was minus 20%. She had not taken thyroid extract all summer because her Camp Doctor volunteered the information that thyroid was injurious to the heart. Upon reassurance, thyroid therapy was resumed, with immediate cessation of the symptoms; her maintenance averages one grain of Armour's Thyroid a day. Her last basal rate was minus 11%.

SUMMARY

1. A woman suffering from migraine and epilepsy had two daughters subject to migraine, one with the abdominal type and the other the cephalic. Hypothyroidism, without the picture of myxedema was found in all three. They promptly responded to thyroid replacement therapy.

2. Of the many theories regarding etiology, the most plausible is, inherited allergic susceptibility with superimposed exciting causes—endocrine imbalance the most prominent. The frequent low metabolic readings are significant of lowered thyroid function. The symptomatic relief produced by Ergotamine Tartrate may be due to its suddenly boosting endocrine function.

3. For the recognition of the hypothyroid state, it is important that basal readings be made as near as possible to an approaching attack and never immediately after.

4. We can only hope for ultimate solution of the migraine problem through coordinated investigations, inclusive of all mechanisms possibly concerned in its production, instead of isolated and fragmentary studies by specialists concerned only with enthusiastic revelations in their respective fields, taking no cognizance of the subtle complexities involved.

Phenolphthalein

By

HORACE W. SOPER, M.D., F.A.C.P.

THE toxicity of phenolphthalein has received considerable attention and aroused much discussion. Fantus and Dyniewicz (1) gave one thousand single doses of the drug and collected the urine and conclude that phenolphthalein does not produce albuminuria.

Zoltan von Vamossy (2), who discovered the cathartic action of the drug, insists that it is not harmful in laxative dosage.

Newman (3) collected seventeen types of atypical phenolphthalein skin eruptions as well as other evidences of toxicity such as lipoid nephrosis, toxic nephritis, visceral hemorrhages and ulcerative colitis. He states that "phenolphthalein is contained in more than one hundred and twenty-five proprietary preparations put up in the form of laxative drugs, chewing gums, confections, fruits and biscuits. It is also used for pink icing on cakes, for coloring of candies, and in pink mouth washes and dentifrices. Hence when exudative lesions of obscure origin are present phenolphthalein as the etiologic agent should be considered."

Belote and Whitney (4) list one hundred and three proprietary preparations which contain phenolphthalein. They discuss the pathogenicity of the drug particularly in regard to the skin and mucous membranes.

My experience as a clinician had given me a strong impression that the habitual use of the drug as a laxative is harmful to a large percentage of the patients who employ it. To clarify the matter I examined one thousand consecutive case records of patients who presented themselves to the clinic with symptoms referable to the digestive tract. (Feces analysis is made in each case regardless of the symptomatology). I wished to determine the effects of the continuous daily dose of the drug over a period of two months or more, excluding those cases in which a single dose produced toxic symptoms such as skin eruptions, etc.

The study disclosed that one hundred and seventy-seven patients had taken daily doses of the drug for a period of time varying from two months to two years. One hundred and fifty-two of these patients suffered from catarrhal colitis. Twenty-two of these patients did not present evidence of catarrhal colitis. Three of these patients presented a chronic stomatitis.

Catarrhal colitis is a frequent diagnosis in our clinic. It is characterized by the presence of excess of mucus more or less intimately mixed with the feces, in clumps of which are found, microscopically, pus cells and occasional blood cells. Proctosigmoidoscopy in many of the cases reveals a generally congested mucous

membrane. The patients in whom the feces are not formed and which contain only excess of mucus are not classed as catarrhal colitis. The usual subjective symptoms of catarrhal colitis are fatigue, irregular fecal evacuations, excess of colonic gas, and vague abdominal discomfort: many patients present evidence of malnutrition and weight loss.

Three hundred and seven of the one thousand case reports disclosed catarrhal colitis.

152 cases as stated above were addicted to phenolphthalein.

73 cases of protozoan or flagellate infestation.

9 cases of *Lamblia Giardia* infestation.

10 cases of anacid gastritis.

6 cases of achylia gastrica.

40 cases of addiction to other purgative drugs.

17 cases in which the etiologic factor was not determined.

307

Catarrhal colitis produced by purgative drugs is quickly cured by withdrawal of the offending irritant, and proper measures for the restoration of normal colon function.

The cases of stomatitis had been very rebellious to treatment, but responded when the phenolphthalein was discontinued.

CONCLUSIONS

Over fifteen per cent of the patients (177) in the gastro-enterologic clinic employed phenolphthalein as a habitual laxative. In a large percentage (152) a diagnosis of catarrhal colitis was made.

A small percentage (22) had established a tolerance for the drug and exhibited no signs of toxicity. Chronic stomatitis was present in three patients addicted to the drug.

Considering the large number of preparations of phenolphthalein in the market, the physician must be on guard in his selection of laxative drugs. Many of the manufacturers of agar and oil mixtures slip in a dose of phenolphthalein to make the preparation more active, thereby deluding the doctor, who believes that he is prescribing a nonirritant mixture.

A Study of the Diseases in the Negro with Particular Reference to the Gastro-Intestinal Tract

By

I. C. SHARON, M.D., M.Sc. (Med.)
CINCINNATI, OHIO

ALTHOUGH gastro-enterology has made rapid strides in recent years, nevertheless, the exact etiology of most gastro-intestinal diseases still remains obscure. Year by year, fragments of knowledge have been added and various relationships have been shown to exist, but there is not, as yet, sufficient information to definitely point to the causative factors. This study attempts to throw further light upon the predisposing factors of the various functional and organic gastro-intestinal conditions by the method of approach which seeks to evaluate racial and constitutional factors as seen in the Negro. Since chronic peptic ulcer is one of the major concerns of the gastro-enterological internist, particular emphasis will be placed upon it.

A problem of this kind necessarily raises the question whether or not there exists any racial immunity or susceptibility on the part of the Negro to certain diseases. If we believe in the theory of evolution, that all men sprang from common ancestors and that surviving anthropologic forms through natural selection came to possess certain superior attributes, biologically speaking, which allowed them to overcome the stresses and strains of unfavorable environmental influences and to survive at the expense of less adapted environmental types, then it seems that we are justified in comparing the resultant characteristics of the various races with their respective incidence to diseased states, with the hope of finding certain predisposing factors which might affect the susceptibility to these diseased conditions. In other words, autochthony working over thousands of years has evolved groups of people throughout the world who have become distinctive in appearance, in innate characteristics and in their immune reactions to disease-producing agents in their aboriginal environment, and it should be possible to uncover some of these factors. Pearl (1) has presented evidence indicating the great importance of the evolutionary history of the human body in influencing human mortality.

Investigators have been struck with the unusual tendency of the Negro towards certain diseases and with the infrequency with which other diseases manifest themselves in him. A perusal of statistical literature shows a high incidence in the colored of tuberculosis, syphilis, tetanus, keloid formation, uterine fibroids, yaws, sleeping sickness, elephantiasis, etc. On the other hand, there is a noticeable decreased incidence of renal and gall bladder calculi, prostatic hypertrophy, most of the diseases of the alimentary tract, erysipelas, yellow fever, scarlet fever, diphtheria, measles, chorea, toxie goitre, refractive errors, trachoma, ovarian tumor, varicocele, baldness, carcinomata in general, etc. Furthermore, the Negro often reacts differently to his disease. We are all aware of his difference in reaction to tuberculosis, which is apt to be of the rapidly progressing type and in which the evidences of resistance are not marked. Despite the greater incidence of syphilis among the colored, there are relatively few cases of locomotor ataxia among them. Sickle-cell anemia is almost exclusively found in Negroes. Regardless of the cause, there is enough unanimity of opinion among the various writers to dispel any doubt that there exist distinct differences between Whites and Negroes in morbidity and mortality from certain diseases.

Dublin (2) has quoted statistics from the Metropolitan Life Insurance Company showing definite differences in death rate, particularly in certain diseases, between the white and colored races. Pearl (3, 4) has shown from statistics on autopsy material from Johns Hopkins Hospital, that there are distinct differences in the pathology between Whites and Negroes, both in incidence and in organological distribution of pathological lesions. The total mortality in Negroes from diseases of the alimentary tract and its associated glandular organs was proportionately smaller, while that attributable to circulatory and respiratory diseases was higher. Pearl has been impressed with the difference between Whites and Negroes with respect to malignant disease, in incidence and selectivity of organs. He found that malignant tumors and malignant metastases occur relatively more frequently among Whites, and that in Whites the primary growths tend to be more distributed throughout the various organ systems. Although the total number of cancers was relatively smaller in the Negro, the relative incidence in the alimentary and reproductive systems was higher, because cancer in the Negro tends to be concentrated in these two systems. These variations in neoplastic diseases suggest to Pearl that there are biological differences in constitutional pattern between Negroes and Whites.

Love and Davenport (5), army investigators, state that the nervous system of Negroes shows fewer cases of instability than that of the Whites, and that the incidence of functional disturbances in the Negro is comparatively low. Rosser (6) has emphasized the racial predisposition of the Negro to develop adult connective tissue, and he has called this the "fibro-plastic diathesis." He notes that in protologic cases this tendency is manifest as external fibrous growths and internal fibrous strictures, so commonly seen in Negroes. Rosser also points out the infrequency of hemorrhoids in Negroes. Miller (7) and Alsbrook (8) have noted gynecologic differences between Whites and Negroes. Paskind (9) concludes from a comparative study of the action of atropine in the white and colored races, that the Negro is less susceptible to the central action of atropine, as evidenced by a slower response in the change of the heart rate.

This qualitative and quantitative variation of the Negro in reaction to various diseases entails for its proper elucidation a careful analysis of all possible differences that may exist between the Negro and the Caucasian—anthropological, anatomical, psychological, pathological, environmental, social, economic, etc.

ANTHROPOLOGY OF THE NEGRO

The Negro race, as we know it, is one of the three outstanding divisions of the Negroid stock (10). The other two divisions are the Oceanic Melanesians and the Dwarf Black or Negritos. Certain skeletal remains of the so-called Grimaldi race, which flourished during the Aurignacian period of the Old Stone Age are probably evidences of a Negroid stock. Neither the ancestors nor the descendants of these early peoples have been traced, but the discovery of the remains indicates a differentiation of the type at a period antedating the birth of Christ by some

twenty to twenty-five thousand years. The relationship of this primitive group to the other races has not been made out.

According to the Spanish historian, Las Casas, quoted by Matas (12), the first Negro slaves who were introduced from Africa to the New World were landed in Santo Domingo in 1505. With the exception of some tribes of Caribs that still inhabit the Gulf coast of Central America and some islands of the Caribbean Archipelago, all the Negroes on the American Continent are directly descended from the black slaves imported from Africa during the slave trade (12). The history of the Negro in the United States dates back to August, 1619. A great many Negro sub-groups were introduced into the American Colonies—the Senegalese, Yolloff, Bambara, Mandinga, Congo or Guinea, Arada, Caffre, etc.—and these types differed slightly in their physical and mental characteristics. The four classes of Negroes today are principally the Guinea Negro, the Yolloff, the Caffre and the mulatto. The relatively pure African types are, however, extremely rare because there has been such a great intermixing of these types, both amongst themselves and between the white race. It has been estimated that out of the twelve million or more Negroes in the United States, ten million are mulattoes (13).

Most anthropologists deny that there is such a thing as a pure race. Boas (14), who is one of the principal proponents of this contention, points out, that from a purely biological point of view, there is no such a true concept as race unity. He goes on to say: "The multitude of genealogical lines, the diversity of individual and family types contained in each race is so great that no race can be considered as a unit. Furthermore, similarities between neighboring races and, in regard to function, even between distant races, are so great that individuals cannot be assigned with certainty to one group or another." Taking this factor into account plus the tremendous miscegenation which has occurred in the past two hundred years, one is obliged to use the term "race" in only its broadest sense when referring to the Negroes as a distinct group. We regard and classify a person as a Negro when he has the slightest trace of negroid characteristics, which are dominant according to Mendelian inheritance, even though he possesses seven-eighths of white blood and reacts to all intents and purposes as a Caucasian. Whenever, therefore, the term "Negroes" or "Negro race" is used in this discussion, it is to be understood that what is meant is a group, highly mixed in racial stock and ancestry, who possesses the so-called negroid characteristics.

ANATOMICAL PECULIARITIES

Most of the anatomical peculiarities of the Negro are readily recognizable and constitute the chief elements for what we know as negroid characteristics. The Negro is usually tall in stature, and has a narrow head and prognathous jaw. The skin is dark brown, the hair is woolly and makes a close curl, the sclerae are muddy, the lips are thick and fleshy and the nose is broad and flat. The auditory canal is usually very straight. The sweat glands and sebaceous glands are highly active. The excessive activity of the sebaceous glands gives a peculiar oily lustre to the skin, and this oily exudation has a very strong odor, which is strongest in the most robust. The subcutaneous layer is thick, and the submucous connective tissue is more developed (12).

In addition to the more or less obvious anatomical differences between Negroes and Whites, statistical data reveal that in the Negro the chest circumference is somewhat less (owing to a reduction in anterior-posterior diameter), the nipples are slightly higher, the pelvis is narrower, the iliac crests are lower, the suprasternal notch is slightly higher, the extremities are relatively longer, the hair line is lower on the forehead, and the interocular breadth and interpupillary distance are greater (15). Todd (15) has shown that certain physical features of the Negro, mostly

in the face, are relatively little altered by interbreeding with other human stocks. He calls these "entrenched Negro features" and cites, as examples, the nasal breadth, the thickness of the lips, the mouth width, the interpupillary distance and the ear height. On the other hand, pigmentation, head breadth, total facial height and nasal height are readily modified by hybridization. Herskovits (16) has also pointed out from physical measurements on large numbers of Negroes that there is a large degree of homogeneity in spite of the great intermixing which has occurred.

Bean and Baker (17) have reported that the spleen is smaller in Negroes. This has been confirmed by Pearl and Bacon (18) and later by Moon (19). Bean and Baker (20) have also reported that the liver is smaller in Negroes than in Whites. Bean (21), in a comparative study of White and Negro brains, found certain racial differences, but these differences could not be verified by Mall (22).

The deep pigmentation of the skin, which is so striking in the Negro, is not fully understood. It consists of pigment granules distributed throughout the lowermost layers of the epidermis. There is estimated to be about one gram of this pigment, melanin, in the whole skin of a Negro (23). Melanin is an amorphous, organic, colloidal dyestuff which contains the indole ring. It is insoluble in water and in organic solvents. It is capable of reducing certain metallic salts, particularly silver nitrate. The melanin-producing cells, melanoblasts, contain a ferment, an oxidase, which is the sine qua non in melanin formation (24, 25, 26, 27). According to Bloch (25), this ferment converts the colorless substance, 3, 4—dihydroxyphenylalanine, which he has called "dopa," to melanin, which colors the cell black (dopa reaction). This particular ferment, dopa-oxidase, is specific for dopa only, and is present exclusively in cells of melanin-producing tissue (25, 27). Whenever dopa-positive cells are increased in number, we have an increased activity of pigment formation, and vice versa (27). The darker the skin, the more abundant are the dopa-positive cells. Thus in the Negro the dopa-positive cells are very numerous, while in the albino, they are absent. The ultimate source of melanin, directly or indirectly, is probably tyrosine (24). A relation between melanin formation and the endocrine glands is suggested by the increase in skin pigmentation which so frequently occurs during pregnancy. There appears to be a very close resemblance, perhaps an identity, between the raw material for the manufacture of melanin and that which forms adrenaline (23, 26). Melanin is highly dependent upon the suprarenal glands, and it is probable that when adrenaline is not formed, pigment appears in its place, as for example, in tuberculosis of the suprarenals.

PSYCHOLOGICAL TENDENCIES

Many writings have appeared in the literature recently stressing the relation of psychogenic and neurogenic factors to various diseases, and it becomes necessary to consider the psychological reactions of the Negro, in order to see what effect they might have upon influencing his autonomic and cerebro-spinal nervous mechanism.

Odum (28) concluded from his study that the Negro easily responded to pleasurable stimuli in an impulsive way, but that he lacked perseverance and self direction and was more or less indifferent to anything bordering on the profound.

Matas (12), in a very extensive paper on surgical peculiarities of the Negro, was impressed with the unique reaction of the Negro to operations. He believed that there is a lessened sensibility of the nervous system on the part of the Negro to pain and shock, but that the emotional side is well developed, and that there is in him a certain tendency to fatalism which leads him to accept accidents and illness with all their consequences as parts of the inevitable. Furthermore, he believed that there is a native

and characteristic indifference, which more certainly relieves the Negro from worry as to the future than is likely to be the case with the white man.

Beckham (29), of Howard University, mentions what he calls the "Negro complex." "This complex is not necessarily identical with inferiority complex," he says: "It is an emotional sublimation that enables the Negro to escape dire reality. In this state he is able to simulate happiness."

Many psychological tests have been employed to obtain scientific confirmation of psychological racial differences, but there is no unanimity of opinion among authorities either as to the value of these tests or as to their interpretation. Klineberg (30) calls attention to many factors, independent of race, which may account for some differences in the results of various investigators—familiarity with the English language, culture, social and economic status, rapport between subject and the one administering the test, motivation (is the subject doing his best?), factor of sampling, etc. Darrow and Heath (31) could find no relation between temperamental type, as defined by questions used in psychological tests, and physiological responses to various stimuli, as measured by galvanic skin reflex, blood pressure, respirations, etc.

Patrick and Sims (32), after administering psychological tests to Negro and White college students in four universities, including two Negro universities, conclude that there are statistically reliable race differences between the Negroes and the white group in introversion. They find that there is a tendency for Negroes to be less introverted and more dominant than the white group. Hurlock (33), in testing White and Negro boys of the seventh and eighth grades, using a modification of the Downey Will-Temperament Test, finds that White boys are speedier in decision and movement and possess greater volitional perseverance than Negro boys, but that Negro boys, on the other hand, possess greater self confidence, finality of judgment, motor inhibition and power of coordination of impulses. She concludes, on the basis of her findings, that differences in temperamental traits do exist between Negro and White children. The results of McFadden and Dashiell (34) are very similar, but the differences are not as marked.

Davenport (35) concludes from his studies of fairly large samples of Whites and Negroes, living under similar social and economic conditions and having about the same amount of scholastic training, that there are distinct differences in mental output between these two races. He believes that these differences are racially innate, and are probably dependent upon differences in the structure of the sense organs and nervous system, which do not reveal themselves as readily as the physical differences.

Although psychological racial differences are not marked and clear-cut, yet there is sufficient data to indicate that there is a tendency toward unique psychological responses in the Negro race.

ENVIRONMENTAL AND RELATED EFFECTS

The Negro seems evolutionally attuned to torrid geographical regions and can work in many places where the White cannot, for he is relatively immune to heat stroke and sun stroke. Taylor (36), who has written many articles on the Negro in relation to his health, has stressed that the Negro is unfit to live in cold climates and doesn't flourish well above the Mason and Dixon Line.

Huntington (37) has shown that there is a distinct relationship between human activity and climate—where the weather and temperature is more variable (stimulating), there tends to be greater human activity, energy and achievement. He points out that the native races within the tropics are dull in thought and slow in action, and that a change, an overstimulation, has occurred in those Negroes who have gotten away from their indigenous environment. He believes that just as the White men do not react well to the tropics, so is there an unfavorable re-

sponse of the Negroes to more stimulating climates. Dowd (38) has noted a relationship between psychological reactions of the African Negro and the climatic zone in which he lives. It has been succinctly said that climate calls the tune to which living creatures dance.

Mills (39) has stressed the importance of climatic factors in various diseases. He is of the opinion that individuals have optimum climates to which they are best suited, and that a stimulating climate, where there is a great variability of the weather and temperature, causes, in those unacclimated or unfitted, an excessive environmental excitation of bodily function. This, he believes, eventually produces general physiological exhaustion which becomes manifest in various diseased conditions, such as exophthalmic goitre, pernicious anemia and diabetes. Mills also points out variations in the female sex function with variations in climate. Englemann (40) has shown a trend toward earlier puberty for Negroes as one passes from the tropics up through the southern and central states to New England, with its greater temperature and weather variability. It indeed appears likely that too violent a climate can produce functional hyperactivity, especially of the nervous and endocrine system.

Wood, Jones and Kimbrough (41) have found geographical variations in the incidence of heart disease. They report that rheumatic heart disease is almost twice as common in Massachusetts as in Virginia, but that hypertension as an etiologic factor is somewhat more prevalent in the latter state. These authors also report that organic heart disease is almost twice as common in the Negro as in the White, but that the reverse is true in angina pectoris, despite the fact that syphilis and arteriosclerosis are such important etiologic factors in cardiac disease in the Negro. It is interesting in this connection to note that Johnson (42) found slightly more than one-third as many cases of marked coronary sclerosis, in autopsy records of patients above the age of 39, in Negroes as compared to Whites.

Diet certainly plays a tremendous role in influencing the state of health of an individual, but just how great a factor it is in inducing certain clinical entities, particularly diseases of the digestive tract, is very difficult to evaluate. McCarrison (43) has advanced the hypothesis that many of our present-day gastro-intestinal disorders are due to faulty food, which has come about by our highly civilized methods of living. It is interesting that in the nine years that he spent in the midst of several isolated races in a remote part of the Himalayas, far removed from the refinements of civilization, he never saw among them a case of asthenic dyspepsia, peptic ulcer, appendicitis, mucous colitis or cancer, although he performed on the average of 400 major operations yearly. He noted that these natives used no alcohol and very little sugar, and that they subsisted mostly on milk, eggs, grains, fruit and vegetables. Because of economic reasons, one of these groups moved to another geographical section where simple fresh foods were not as easily obtainable, and McCarrison was surprised to observe that they soon developed disorders which were previously unknown to them. McCarrison is of the opinion that a faulty diet is not the basis of such disturbances as diarrhea, dysentery, gastric and duodenal ulcer, intussusception, gastric dilatation, colitis and failure of colonic function. He has performed animal experiments which give further evidence in this regard. Boland (44), who has reviewed a large series of white and colored patients in the South, reports that in Whites the incidence of appendicitis is six times that of the Negro, while the incidence of peptic ulcer is twice as great and that of biliary tract disease is ten times as great. He agrees with McCarrison, and attributes these differences to a more wholesome diet of the southern Negroes—a diet which he says is similar to that of McCarrison's East Indians.

While it cannot be denied that diet plays an important

part in producing gastro-intestinal derangements, yet the differences in the incidence of diseases between Negroes and Whites are so great and so consistent, even in large urban communities where the Negro of necessity eats the food of modern civilization with his white neighbors, that it is extremely unlikely that dietary factors can account for the statistical variations. Rivers (45), in studying a group of Negroes in central Texas, was impressed with the rarity of peptic ulcer syndrome among them, yet he found that their diet was unbalanced, they ate whenever they could and whatever they could get, they lived under pathetic hygienic conditions, they dissipated recklessly, their habits invariably included the abuse of tobacco and alcohol and their hours of sleep were very irregular.

Although social and economic factors do not concern us much in a study of this kind, nevertheless, they do exert considerable weight indirectly. Many of the factors previously mentioned are obviously greatly influenced by social and economic conditions. Herskovits (46), who has probably made the most comprehensive study of the physical anthropology of the American Negro, points out that there is even a social factor in the formation of the type of the Negro. He finds that for the most part dark Negroes marry light-colored women, and he believes that this is due to the conscious or unconscious desire for light skin, which becomes synonymous with social elevation, lack of prejudice and greater opportunity.

It appears from statistical and other evidence that a change has been gradually occurring in the incidence of various diseases in the colored race. The general morbidity and mortality were less than that of Whites in the South during the whole period of slavery, up to the time of emancipation, but there has been a great increase since 1864, and now the rates for the Negroes are generally higher than those of the Whites (2, 12).

Miscegenation with the White race no doubt plays a large role in these variations. The opinion has been expressed by many writers that hybridism greatly increases the general susceptibility to diseases. Matas (12) has found that dental caries and alveolar abscesses are relatively rare in the dark Negro but common in the light mulatto, and he also expressed his belief that syphilis is less virulent and less fatal in relatively pure Negroes. Hoffman (47), discussing race amalgamation, said: "Whatever the race may have gained in an intellectual way, which is a matter of speculation, it has been losing its greatest resources in the struggle for life, a sound physical organism and power of rapid reproduction."

Hoffman (48) has very comprehensively reviewed the racial factors in cancer, and points out, that although malignant tumors were very infrequent in the slave population and are rare in practically all parts of present-day Africa, the present cancer mortality in the Negro is rapidly rising and is approaching that of the Whites. Tuberculosis was said to be unknown among the savage tribes of black men that inhabit the meagerly-explored regions of equatorial Africa, and among those who lived on the coast of Guinea in the early days of the slave trade before colonization by white men (12). Although recent figures show a decline in morbidity and mortality rates from tuberculosis in Negroes, there is still more than two and a half times the incidence in Negroes as compared to the White race. Similar changes are apparent in hypertension. Donnison (49) rarely saw hypertension in an African native, but reports now indicate the great incidence of this condition in American Negroes (41, 50, 51, 52). Pollock (53) has indicated the relative and absolute increase of mental diseases in the Negro in the United States from 1910 to 1923, especially in the North. Although diabetes mellitus was formerly a rather uncommon condition in Negroes, the mortality rate is now almost that of the Whites (2). Leopold (54) shows evidence that in the female sex diabetes is even slightly more common in the colored race. Similarly cases of hemophilia (55) and

pernicious anemia (56) in the Negro have recently been reported in the literature, but there is some doubt whether these conditions have ever been seen in a relatively pure-blooded Negro, although the case of hemophilia reported by Crandall (55) may be one of these extremely rare cases. Cases of Addison's disease in the Negro have also recently appeared in the literature (57), bringing the total number of reported cases to fourteen. It arouses speculative interest that, although tuberculosis is the etiologic factor in the vast majority of cases of Addison's disease and in spite of the great incidence of tuberculosis among the colored population, Addison's disease in the Negro is extremely uncommon.

The Negro is becoming more and more a part of the hustle and bustle of modern civilization, with its increasing responsibilities, greater psychic and mental stimulations and faster methods of living, and it is very likely that this is an important factor in the increasing incidence of certain diseases among Negroes. The opinion expressed by Moschowitz (58), that such diseases as essential hypertension, Graves syndrome, gastric and duodenal ulcer, cardiospasm and irritable colon are of psychogenic origin, is very persuasive and is corroborated to a certain degree in the Negro, in that these diseases have steadily shown an increase in the colored race since the abolition of slavery when the Negro has had to compete with the Whites in the economic struggle for existence.

STUDY OF CASES

The records of all Negro patients admitted to the gastro-intestinal service of the Graduate Hospital of the University of Pennsylvania during a five year period were completely surveyed. During this period the total number of admissions to the Graduate Hospital on all services was 37,324. Of this number 7,480 (20%) were colored patients, of which 4,529 (12%) were females and 2,951 (8%) were males. The total number of admissions to the gastro-intestinal service during this time is, unfortunately, not easily available. The total number of colored gastro-intestinal patients who were studied during this period was 115 (Tables I-V incl.), and this represents many and multiple readmissions, many of these patients, especially those with peptic ulcer, having been admitted more than three times during the five years. These patients have been divided into groups, showing the sex ratio, average age, and percentage of each group (Table VI). Although these patients constitute the vast majority of colored patients admitted to the hospital with gastro-intestinal symptoms, yet it should be pointed out that some patients with digestive disorders may have been on other services (medical, surgical, etc.), either because the digestive complaints were minor to some other complaint or else because of a mistaken diagnosis at time of admission. Nevertheless, it is felt that this data represents a cross section of the gastro-intestinal diseases in the colored race in Philadelphia. It is unfortunate that the material from which this data is drawn does not allow a differentiation between relatively full-blooded Negroes and mixed bloods, and it is hoped that in the future this discrimination will be made.

Considering the number of patients studied, regardless of the number of admissions, the Negroes constituted 27% of carcinomata of the stomach (Whites 27, Negroes 10), 13.5% of duodenal ulcers (Whites 121, Negroes 19), 16.6% of gastric ulcers (Whites 37, Negroes 7), 7.3% of cholelithiasis (Whites 101, Negroes 8) and 11.1% of idiopathic ulcerative colitis (Whites 32, Negroes 4). Taking into account that the

Negroes constituted 20% of the total number of admissions, these figures tend to show a greater incidence of gastric carcinoma and a lower incidence of peptic ulcer and ulcerative colitis in the colored race, while there is a marked decreased incidence of cholelithiasis in the Negro. There was only one Negro patient out of the 115, in whom a primary diagnosis was made of a functional disturbance. The rarity of mucus and spastic colitis and of the various gastro-intestinal neuroses in Negroes seen at the Graduate Hospital in previous years has been mentioned before (59).

Many writers, particularly in the South, have noted the infrequency of peptic ulcer in the Negro (44, 45, 51, 60, 61, 62, 63, 64). However, Steigmann (65), in a recent study at Cook County Hospital, found no appreciable racial difference in the incidence of peptic ulcer, and he believes that the Negro is just as susceptible as the white person when he is subjected to the same environmental, psychogenic strains, such as are present in industrial centers. Jaffe (66), working in the same hospital, found on autopsy material that, although peptic ulcer was a more frequent cause of death among white people, there was about the same incidence on routine autopsies. The probable reasons for this variation in statistics will be alluded to later.

Many theories have been advanced to explain the genesis of peptic ulcer, and these have been briefly summarized by Stix (67), as follows: (1) Gastritis theory, first advanced by Cruveilhier in 1829 (Proponents: Konjetzny, Faber, Korbsch, Puhl, Kalina, etc.). (2) Neurogenic theory, first advanced by Rokitsansky about 1845 (Proponents: V. Bergman, Cushing, Westphal, Robinson, Levison, etc.). (3) Circulatory theory,

first advanced by Virchow in 1853. (4) Mechanical theory (Aschoff, Bauer). (5) Infectious theory (Roscnow, Billings, Passler). (6) Peptic theory (Buchner, Sippy). (7) A combination of two or more theories (Rivers, Westphal, V. Bergman, Krehl, etc.).

In all probability peptic ulcer is a constitutional and systemic derangement, in which gastric manifestations are predominant. Rivers and Vanzant (68) have pointed out that many patients who first present themselves with symptoms of peptic ulcer do not have peptic ulcer, but are of the same type in which peptic ulcer is found. These patients often turn up later on with demonstrable peptic ulcer. The relation of body type and constitutional build to various diseases, which was first brought to attention by Stiller (69), has been stressed by Draper (70, 71) and others with regard to peptic ulcer. However, Feigenbaum and Howat (72), after evaluating their anthropometric studies, do not believe that there are distinctive, anatomic characteristics of patients with either peptic ulcer, cholecystitis or diabetes mellitus. Nevertheless, regardless of body type, it is well-recognized that peptic ulcer is generally associated with an unstable vegetative nervous mechanism, in which the parasympathetic division is usually predominant.

The familial tendency to develop peptic ulcer is well known and suggests a genetic factor. Dickinson (73) has cited five children in the same family with peptic ulcer, all of them being of the asthenic habitus. Meyer, Maskin and Necheles (74) found in testing the gastric acidity of 82 healthy relatives of ulcer patients that most of them exhibited either too little free acid or too much free acid.

Rivers (45) has thoroughly discussed the factors in

TABLE VI

the genesis of peptic ulcer, and emphasizes the ambitious, intensive, and high-strung characteristics of peptic ulcer patients. The Negroes, as a general rule, as has been previously brought out, are not of this type, but it is certainly conceivable that under increased environmental stimulations, they may react inwardly and outwardly as violently as anyone else, and thus predispose themselves to various psychogenic disorders. Differences in reactivity, in emotional responsiveness and in temperament are only differences in threshold or degree and an emotionally sluggish person will respond as intensely as the most extreme individual of the opposite end of the distribution

curve, provided the stimulus is sufficiently raised (13).

Psychogenic factors in the production of peptic ulcer have been stressed in many recent writings (45, 58, 63, 64, 65, 75, 76, 77). In fact, Robinson (78), giving an etiological classification of gastro-duodenal ulcerations, even suggests substituting the term "psychogenic ulcer" for common chronic peptic ulcer. That emotional disturbances have a profound effect on the various functions of the body has been emphasized by Cannon (79), Alvarez (80, 81) and others. Pavlov (82) demonstrated psychic effects on the physiology of digestion in animals long ago. It is doubtful, however, whether animals ever develop chronic peptic ulcer

as we know it in man, although Fox (83) has described ulcers in captive wild mammals, particularly in Primates and Carnivora, which resemble human peptic ulcer. There seems little doubt that psychogenic factors are definitely related to peptic ulcer, and if we are to believe that the Negro is innately less responsive to psychogenic influences, then we would expect to find a decreased incidence of peptic ulcer in the colored

39 years of age showed evidences of arteriosclerosis, and only three of these were luetic. In three out of the four patients who had both gastric and duodenal ulcers there was a positive Wasserman.

Bockus (59) has pointed out that peptic ulcer symptoms in the Negro are usually less classical, and that the amount of pathology found at operation and autopsy is often greater than what one might expect.

TABLE VIII
40 patients with peptic ulcer

race. In order to get a more accurate estimate of peptic ulcer in the Negro, additional cases were taken from the previous five year period, which had not been recorded in the later years (Table VII). The total number of ulcer patients during the ten years, regardless of the number of admissions, was forty (Table VIII). There were 28 cases of duodenal ulcer (19 males, 9 females), 8 cases of gastric ulcer (4 males, 4 females) and 4 patients in whom both gastric and duodenal ulcers were at some time found (all males). The ages ranged from 15 to 63 and were quite dispersed throughout all the age groups. There was a slight tendency for an increased incidence in the older ages, eleven (27.5%) being 48 or over. The average age for the duodenal ulcer group was 40.0, that for the gastric ulcer group was 40.5, while in the patients having both gastric and duodenal ulcers, the average age was 38.3. The majority of these ulcer patients, especially those in the later years of this study, when we have become more "gastritis conscious," showed evidences of chronic gastritic changes, as evidenced by a dirty gastric residuum containing many epithelial and pus cells, by fuzziness and irregularity on roentgenographic examination, and in many cases by gastroscopic appearance. Five of the patients (12.5%), all males, had at some time an acute perforation of their ulcer (3 gastric, 2 duodenal). Four patients (10%), 1 male and 3 females, were admitted with gross bleeding (3 duodenal, 1 gastric). Twelve patients (30%) had evidences of pyloric obstruction (8 duodenal, 1 gastric, and 3 with combined ulcers). Eleven of the patients (27.5%) at some time underwent an operation for their ulcer. There was nothing characteristic or remarkable about the blood pressures. On gastric analysis most cases showed varying degrees of hyperchlorhydria, while the remaining ones exhibited generally a high normal free acid. There were no cases of achlorhydria, and in only one case was there less than a normal acidity. Sixteen of the patients had a positive Wasserman reaction, eighteen showed no evidences of lues, and there was no record of the remaining six. The ulcer patients with lues occurred mostly in the younger age group. Most of the patients passed

He has also been impressed with the greater frequency with which syphilis and tuberculosis act as causative factors in producing pathology in the upper gastrointestinal tract in Negroes, even though these lesions are rare. Bockus doubts if he has ever seen peptic ulcer in a pure-blooded Negro, who did not have in association either advanced gastritis, syphilis, marked arteriosclerosis or tuberculosis (94).

Although syphilitic lesions are rare in the gastrointestinal tract, one often wonders what part syphilis may play as a predisposing factor to other conditions or in influencing certain diseases, such as peptic ulcer, with which it may be coincidentally associated. It is interesting that visceral syphilis, except cardiovascular involvement, practically never occurs concomitantly with para-luetic manifestations (tabes or paresis) (95). In the present series of 115 cases, 50 cases showed definite evidence of syphilis, 3 cases were questionably luetic. 52 cases showed no evidence of involvement and 10 cases were not recorded. In nine cases in which syphilis was associated it was felt that the luetic factor played some part in the symptomatology. (Cases 23, 24, 25, 30, 34, 65, 68, 110 and 111). Bockus and Bank (96) have reported cases of upper gastro-intestinal diseases associated with syphilis which did not respond well until after anti-luetic treatment was instituted. They have emphasized the multiplicity of X-ray findings and the presence of retention or stasis in the terminal esophagus or terminal duodenum in those cases in which the lues is playing an active part.

There were ten cases, in this colored series, of carcinoma of the stomach, 8 males and 2 females. The ages ranged from 36 to 61, most of them being around the fifth decade. The average age was 49.1. Nine of these patients showed an achlorhydria, while in the remaining one there was a hypochlorhydria. In most of the cases the lesion was in the antral part of the stomach. All cases showed rather advanced lesions. Fitts (97) has also pointed out the infrequency of finding early gastric carcinomata in the colored race, and, in his

comparative series of White and Negro cases, the Negroes showed more frequently an absence of free hydrochloric acid.

The low incidence of cholelithiasis in Negroes, found in this study, has been often noticed (12, 42, 98, 99, 100). Jaffe (99) has reviewed the literature from various countries, and finds statistics which show that the Negroes and lesser pigmented races all have a lowered incidence of cholelithiasis. He also shows, as do most writers, that cholelithiasis is very infrequent among colored males. In the present series seven cases out of eight were in females.

Eleven cases of so-called catarrhal jaundice were seen during the five year period (5 males, 6 females). Of this number, six showed evidence of lues, while in one the luetic factor was questionable. The ages ranged from 17 to 43, most cases falling between 25 and 35. The average age was 30.9.

SUMMARY AND CONCLUSIONS

Evolution has gradually evolved races of men who are distinctive in appearance and state of reactivity to external influences. Each race has therefore acquired certain tendencies, whereby it is not only able to function best in its indigenous environment, but by means of which it is either able to withstand unfavorable environmental influences or else by which it is made more susceptible to them. These innate biological possessions are present in all men, they differ in all persons only in degree and they tend to be more alike in a given race. In other words, just as races have certain physical peculiarities which distinguish them, so do they also have unique methods of reacting to all of their surroundings.

The Negro, over hundreds of generations in his aboriginal environment, has acquired particular characteristics in appearance and response. He shows anthropological, anatomical, psychological and pathological differences from the white man.

A study of 115 cases of Negroes on the gastro-intestinal service has revealed the following observations:

1. Compared to the white group during the same period there is a slightly lower incidence of duodenal ulcer, a considerable decrease in incidence of idiopathic ulcerative colitis, and a marked decreased incidence of functional disturbances and cholelithiasis. On the other hand, there is a higher incidence of gastric carcinomata in the colored group.

2. In peptic ulcer there was a tendency for more frequent occurrence in the later ages, most cases showed a hyperchlorhydria, and there were evidences, in the majority of cases, of chronic gastritic changes in association. Lues was more frequently associated with gastric ulcer. Acute perforations occurred only in males.

3. In almost all of the cases of gastric malignancy far advanced lesions and achlorhydria were found.

4. Nearly half of the patients showed definite evidence of lues, and in a certain number of cases it was felt that the lues played some part in the symptomatology.

I wish to express my appreciation to Dr. H. L. Bockus, Professor of Gastro-Enterology at the Graduate School of Medicine of the University of Pennsylvania, for his valuable suggestions in the preparation of this paper.

A Practical Method for Determining the Concentration of Buffer Salts in the Body Fluids

By

ANTON W. OELGOETZ, M.D.
COLUMBUS, OHIO

It has long been known that an animal maintained on a full diet from which, however, the buffer salts have been removed will die more quickly than a control animal which receives no food at all. The reason why these buffer salts are so important is because all of the physiologic processes depend upon definite and constant conditions of pH. Trypsin, for example, finds its optimal action at pH 6 to 8, while pepsin cannot function except in the presence of hydrochloric acid at about pH 1.5 to 2. Clinicians have long known that many of the functional disturbances, the pathologic physiologies such as allergy, were secondary to disturbances in the relative concentration of the serum buffer salts. There is urgent need for a practical test for determining the buffering ability of the body fluids.

The concentration of the buffer salts in the blood is always constant and can be determined by chemical methods; however this necessitates 13 different, complicated determinations which makes routine practice clinically impractical. Because the cells of the salivary glands, the stomach, the pancreas, and the kidneys are selective, the normal buffering mechanism of the blood cannot be studied by an analysis of their respective secretions and excretions. The only organ

NOTHING in the animal economy is more constant than the H ion concentration of the blood and fluids which bathe the tissues. When different amounts of acid or alkali are added to water the range of H ion concentration is very extensive, whereas the blood and body fluids remain constant, notwithstanding the continual addition of acids and alkalies from food, and acids which form as a result of metabolism.

The mechanism by which this constancy of pH of the blood and body fluids is maintained is the buffering action of the salts normally contained in these fluids, viz., an acid group, chlorine, iodine, phosphorus, silicon and sulphur, and an alkaline group, aluminum, calcium, copper, iron, magnesium, manganese, potassium and sodium. All of these buffer salts are always present in a definite and constant concentration. When the H ion concentration of the body fluids changes, dissociation of these buffer salts maintains a constant pH of 7.2. The range of the normal buffers is approximately from pH 7 to pH 7.6. As long as the change in H ion concentration remains within this physiological range, it is "compensated" by the normal buffers; when the range is greater than can be corrected by the normal buffers it is "uncompensated."

Submitted November 3, 1937.

in which the secretions and excretions are constantly buffered at pH 7.2, as in blood, is the colon.

EXPERIMENTAL

Instill into the colon, through a urethral catheter, 4 ounces of water at pH 7.2 (neutral). Permit the water to remain in the colon for 20 minutes, then remove and determine (electrometrically) the pH. Normally, it will always be found at pH 7.2.

If 4 ounces of water at pH 10 (alkaline) is instilled and removed in 20 minutes, the pH again will be found at pH 7.2.

If now 4 ounces of water at pH 3 (acid) is instilled and removed in 20 minutes, the pH likewise will be found at pH 7.2.

In short, the mucosa of the normal colon, in the presence of a normal concentration of buffer salts in the serum, maintains the secretions of the colon and the feces constantly at pH 7.2. This experiment can be shortened by simply instilling water at pH 7.2. If upon removal it is found to have remained at pH 7.2, the normal buffering mechanism of the colon is functioning. On the other hand, if the pH of the returned fluid has changed either to the acid or alkaline side, a failure of the buffering mechanism is indicated.

The same experiment can be conducted by instilling a solution of *any known pH* between pH 3 and 10. Normally, in 20 minutes, the pH will be buffered at pH 7.2.

UNCOMPENSATED ALKALOSIS

(Mr. B. N.) Chronic Diarrhea.

Instillation of solution pH 7.2; twenty minutes later, pH 7.6. Instillation of solution pH 10; twenty minutes later, pH 8. Instillation of solution pH 3; twenty minutes later, pH 7.6.

In this case it will be noted that pH is always overcorrected on the alkaline side, indicating a preponderance of alkaline salts which are uncompensated by acid buffer salts. This is a case of uncompensated alkalosis.

UNCOMPENSATED ACIDOSIS

Instillation of solution at pH 7.2; out in 20 minutes—pH 3.2. Instillation of solution at pH 10.5; out in 20 minutes—pH 7.2. Instillation of solution at pH 3; out in 20 minutes—pH 3.2.

In this case there is a failure of the alkaline salts, indicating uncompensated acidosis.

In summary, if a solution at any pH between pH 2 and 10 is instilled into the colon, the normal buffering mechanism of the colonic mucosa will correct it to pH 7.2 if it can; if the serum buffer salts are available in normal concentration. Failure of the buffering mechanism indicates an imbalance in the relative concentrations of the normal serum buffer salts. It should be noted that failure of the buffering mechanism does not necessarily indicate a *reduced* concentration of the acid or alkaline buffer salts, but more often an imbalance in the relative concentrations between the acid and alkaline groups.

However, the above tests are inconvenient and too

time-consuming for routine practice. An easier way to determine the buffering mechanism of the colon is to determine the pH of *fresh feces*. The reaction must be taken immediately after passage of the feces; if feces is permitted to stand an hour, acids and alkalies which no longer come under the buffering action of the colonic mucosa are rapidly formed, making such determination entirely incorrect. Fresh feces can be obtained in the office by injecting an ampule of pitressin.

Because it is thin and therefore easily and quickly affected by a minimum of moisture, litmus paper is the quickest way in which to determine the pH of the feces. If the litmus paper is made up at pH 7.2 (neutral) it is extremely sensitive. It is not necessary to insert the litmus paper *into* the feces, thereby obscuring the color changes; simply to bring one side of the paper into contact with the feces is sufficient. The reaction is easily read on the opposite side of the paper. If the reaction to litmus is amphoteric, the normal buffering mechanism is functioning and nothing more need be done. If the reaction is acid or alkaline (blue to red or red to blue) the buffering mechanism is unbalanced and the exhibition of the normal buffer salts is indicated.

If an exact (quantitative) determination is desired, or if fresh feces cannot be conveniently obtained, the instillation of solution of known pH as described above, must be done. However, for practical purposes it is only necessary to determine the reaction of fresh feces to litmus paper, as the treatment is the same whether the imbalance is on the acid or alkaline side. It has been shown that an uncompensated imbalance of the buffer salts can only be corrected by the exhibition of *all* of the serum salts. The absorption of these salts is regulated by a mechanism which is chemically mutually interrelated, so that the administration of one of them (only) often results in the further elimination of other salts of the group (Macleod). Likewise, pediatricians have long known that the absorption of iron is facilitated by the presence of calcium. If all of the normal buffer salts are exhibited in their relative concentrations as in blood, the normal physiologic relationships are reestablished.

The author has found, however, that if these salts are given by mouth in too great concentration, even though the relative concentrations are quantitatively correct, adverse osmotic pressures are set up in the colon which interfere with absorption. Studies are now under way to determine the proper concentration in which these salts must be administered to be absorbed. This test likewise offers a convenient means for studying the relationship between the serum buffer salts and acid achylia and hyperacidity of the stomach. If this test, which requires but one minute is routinely done, many obscure cases will be found to be secondary to uncompensated acidosis or alkalosis. Further studies along this line will be reported in a later paper.

CONCLUSION

A practical method is described for recognizing uncompensated acidosis and alkalosis.

Terminal Ileitis: Conservative Surgical Treatment

By

ISIDOR KROSS, M.D., F.A.C.S.*

NEW YORK, NEW YORK

IN any disease in which we are ignorant of the etiologic factors, the method of treatment must of necessity be empiric. In the past few years since the appearance of a paper by Crohn and his collaborators, the medical profession has come to recognize as a clinical entity the disease which is now commonly known as regional or terminal ileitis. The etiology of this disease is still unknown, although Felsen (2) considers it part of the group of intestinal inflammatory lesions caused by the atypical dysentery bacillus of Sonné Duval. Because of our lack of definite knowledge of the causative factors, we must fall back upon our clinical experience in formulating the proper therapeutic procedures. Fortunately our knowledge of the pathology of this disease is much more comprehensive.

In the advanced chronic cases we have a clear cut picture in which the following changes predominate. The bowel segment proper has become reduced in caliber. Its soft, supple, consistence has become converted into a rigid induration as a result of the development of a considerable amount of fibrous tissue. As a result of this cicatrization, the lumen of the bowel is markedly diminished and it is this change that produces the characteristic X-ray picture described by Kantor (1). Sinus tracts, having their origin in the ulcerated and necrotic mucosa, penetrate the wall of the bowel and enter (1) into the mesentery producing mesenteric abscesses, (2) into adjacent loops of bowel which have become adherent to one another, (3) into the peritoneal cavity itself where small intra-abdominal abscesses are found, or (4) into the abdominal wall proper, producing abdominal wall abscesses, which generally rupture externally and form the outlet for the original intestinal sinus. The pathologic changes develop slowly thus allowing for the formation of adhesions prior to the development of the necrotizing intestinal sinus formation with its resultant intra-abdominal abscesses and intestinal fistulae.

When the surgeon is confronted with such a picture, there is practically unanimous agreement regarding the method of treatment to be pursued. The changes produced are such that a restitution of the diseased tissue to normal is out of the question. There remains nothing but the excision of the diseased area. Whether this is performed in one or more stages depends upon the general condition of the patient and the character and extent of the lesion. The treatment, however, calls for radical surgery.

The picture in the early or acute case is an entirely different one. Here we have a diffuse oedema of all the layers of the intestinal wall producing a bowel segment one and a half times the size of the normal bowel. The normal color is markedly changed to that of a dull, lusterless, reddish gray. The consistency is that of a

rigid garden hose. The mucous membrane proper shows irregular areas of ulceration and necrosis. The corresponding portion of mesentery is markedly thickened and oedematous and contains large, soft, hyperplastic lymph nodes. In these early cases there may be a considerable amount of clear, straw colored fluid free in the peritoneal cavity. Here the surgeon is confronted by a problem very much different from that which obtains in the chronic advanced case.

There are two schools of thought regarding the proper method of handling the situation. One group maintains that these early acute cases will invariably continue in their inflammatory and necrotic changes and that therefore the proper method of treatment consists in the radical removal of the diseased segment. The other school holds the opinion that many of these early cases can and do undergo spontaneous resolution and that a restitution to normal does occur. For that reason, this group maintains that it is not only worth while but even more advisable to employ conservative surgical measures such as enterostomy or ilio colostomy. This is done with the idea of putting the diseased inflamed bowel at physiological rest, thus giving the natural reparative agencies of the body an opportunity of performing their function. If the disease process can be arrested and cured by this means, this procedure would be ideal. If it does not produce this desired result, and resection is necessary, this can always be done more safely and at more propitious time at a second stage. How frequently and in what type of case, conservative surgery will produce a cure, we will learn only from clinical experience and especially from a meticulous follow-up over a long period of time.

It is for this reason that the report of the following cases should prove of interest and of some value.

The first case to be reported occurred in 1931 before the clinical entity of regional ileitis was described. The patient was a child, twelve years old, who was under the care of his family physician for a period of four weeks for what was diagnosed as intestinal influenza. The chief complaint during this period was indefinite diffuse abdominal pain and general malaise. This was accompanied by nausea and by a low grade fever rising to 101 in the afternoon. About twenty-four hours before his admission to the hospital (Patient: T. R., No. 340971, Mount Sinai Hospital, July 12, 1932) he was seized with a very severe attack of lower abdominal pain that settled in the right lower quadrant of the abdomen. This pain persisted up to time of operation. Physical examination revealed the following: markedly pale, sallow child, who appears washed out. Localized tenderness over McBurney's point, definite spasm over the lower half of the right rectus muscle and rebound tenderness. No mass could be felt.

At operation, July 12, 1932, the appendix was found considerably elongated and oedematous. The distal eight inches of ileum was markedly thickened and rigid throughout, grayish red in color and lusterless in appearance. The appendix was removed and since the bowel proximal to

*Surgeon, City Hospital; Associate Surgeon, Beth Israel Hospital; Associate Surgeon, Montefiore Hospital.
Submitted November 15, 1937.

the inflamed terminal ileum showed no distension, nothing further was done. The post operative course was uneventful and the patient was discharged on the sixteenth day post operative. He has been kept under observation up to the present and there has never been any sign of a recurrence or of a recrudescence of the ileitis.

The second case also occurred in the pre "regional ileitis" period. The patient was 61 years old and for several years had been subject to irregular attacks of pain in the right lower quadrant of the abdomen. He was under the care of Dr. A. A. Epstein who treated him on the basis of mild attacks of appendicitis. His last attack occurred on August 29, 1931. This attack was more severe than usual and he was admitted to the Mount Sinai Hospital September 3, 1931 Patient: J. G., No. 329771) with diagnosis of acute appendicitis. Physical examination yielded spasm of the lower half of the right rectus muscle. There was definite tenderness over McBurney's point. Rebound tenderness was present, especially marked in the right lower quadrant of the abdomen. On rectal examination, a boggy induration could be felt in the right fornix. At operation September 3, 1931, a pseudo myxomatous peritonitis with a ruptured mucocele of the appendix was found. In addition to this, "examination of the intestine showed a loop of small gut about two feet from the ileo-caecal junction which had been in contact with the appendix to be thickened about one-quarter to one-half inch over a distance of about six inches. This thickening spread over the free part of the gut in an irregular fashion so that in places it entirely surrounded the gut and in others was just about three quarters of an inch wide. There was complete lack of elasticity of this portion of the bowel, color was markedly red, no glistening appearance could be seen anywhere and it was covered with a moderate amount of fibrinous exudate. In order to forestall what looked like an inevitable intestinal obstruction as a result of this indurated and apparently parietic gut, an enterostomy was performed about one and a half feet above this area in perfectly normal intestine." This patient has also shown no recrudescence or recurrence of the intestinal lesion up to the present time.

The third case was that of a 48 year old man who was admitted to the Beth Israel Hospital on November 12, 1935 (Patient: M. H., No. 78269). For about eleven months prior to his admission to the hospital he suffered from indefinite attacks of pain in the epigastrium and right lower quadrant of the abdomen. These attacks came on at irregular intervals and had no relation to meals or physical exertion. There was no associated disturbance in the genito-urinal tract. Soon after the onset of these attacks of pain, he noticed a "lump" in the right lower quadrant of his abdomen. This lump was not tender and grew larger very slowly. With the onset of the pain, he noticed a gradual and progressive loss of strength, accompanied by a loss of about forty pounds in weight. At the time of admission to the hospital he presented as the outstanding features on physical examination, a marked asthenia, moderate cachexia, definite signs of loss of weight and a fixed painless mass about the size of a fist in the right lower quadrant of the abdomen. A preoperative diagnosis of carcinoma of the caecum was made and the patient was prepared for operation. This was performed on November 12, 1935. When the peritoneal cavity was opened a free, straw colored fluid was found filling the depth of the

pelvis. Caecum and ascending colon normal in every respect. Appendix small and atrophic, without signs of infiltration. Distal two inches of ileum was soft and normal in appearance. From this point on for a distance of fourteen inches the ileum was doubled upon itself and was about two times the caliber of the rest of the ileum—so much thickened that its lumen could not be felt and the peritoneal coat was dull, dark reddish gray with extremely marked injection of the vessels. The corresponding mesentery was thick, friable and markedly oedematous. Proximal to this portion was a stretch of ileum about eight inches long which was perfectly normal in every respect. Proximal to this normal portion, was a stretch of ileum exactly similar to the inflamed part described above—this was about ten inches long. From there on the rest of the bowel was perfectly normal in appearance and on palpation. Owing to the poor general condition of the patient and to the intensely acute nature of the disease process, it was decided to perform a side tracking operation and to delay for a second stage, the resection of the inflamed bowel if this should prove necessary. The ileum was cut completely across about eight inches proximal to the inflamed tissue to assure a healthy area for the line of incision. The distal end of the bowel was now closed with three layers of inverting sutures and the proximal end was anastomosed to the hepatic extremity of the transverse colon by an end to side anastomoses. The first three post operative days were rather stormy and presented the characteristic picture of a paralytic ileus. With this period over, the rest of the convalescence was uneventful. On the tenth post operative day the abdominal mass could scarcely be felt and on discharge from the hospital on the fourteenth day, all that could be made out in the right lower quadrant was a feeling of increased resistance. This patient has been followed up to date for a period of sixteen months and when last seen was free from all pain, had regained his lost forty pounds and was pursuing his usual rather arduous occupation. No mass could be felt in his abdomen.

SUMMARY

Three cases of terminal ileitis are reported. In one of these the appendix was removed but the diseased bowel was left undisturbed. In a second, the treatment consisted of an enterostomy and in the third the treatment instituted was a side tracking ileo colostomy. These cases have been followed up for periods of five and a half, four and three-quarters and one and a quarter years respectively and in none of these has there been either a recurrence or a recrudescence of the inflammation. While it is true that three cases do not constitute enough from which to draw any general conclusions, I feel that many others must have had similar experiences and that only by an accumulation of the experiences of many surgeons, will the profession acquire the mass of clinical knowledge and experience upon which to formulate proper methods of treatment for this disease.

Karaya Gum as a Mechanical Laxative

An Experimental Study on Animals and Man

By

A. C. IVY, Ph.D., M.D.

and

BERTHA L. ISAACS, B.S., M.B.*

OVER a period of years many different substances have been offered for the management of chronic constipation. Physiologic knowledge and clinical experience have caused a reduction in the use of mineral and vegetable substances which produce their effect by increasing the force and rapidity of peristaltic movements. Instead, there has been an increase in the use of bland, indigestible substances which increase the bulk and moisture of the feces, or which serve as a sort of lubricant, a function that has been ascribed to the lipids normally excreted by the intestine (1). In addition, foods which contain or yield organic acids have been used.

The term laxative is so often used inadvisedly that it seems worth while to consider the meaning of the term. Sollmann (2) in his text on Pharmacology defines cathartics or evacuants as drugs which induce defecation either by (a) increasing the bulk (b) by preventing absorption of water, or (c) by causing irritation of the small or large intestine. Agar furnishes a typical example of the first group, salines of the next, and vegetable cathartics of the last. Sollmann describes laxatives as those substances which increase peristalsis moderately and produce more frequent stools of almost normal consistency without causing irritation. We agree with this description.

There are two general types of mechanical laxatives, (a) non-hygroscopic substances which act by softening the fecal mass thereby facilitating propulsion without definitely increasing the bulk (vaseline and liquid paraffin) and (b) hygroscopic substances which absorb water and expand considerably. Psyllium, agar and bassorin are representative of the second group. We have made a study of one of the substances in the latter group, namely, Karaya gum.

Nature of Karaya gum: Karaya gum is collected from the bark of a tree of the *Astragalus* species (*Stereuliaceae*). It is sometimes referred to as false or Indian tragacanth or *Stereulia* gum. It belongs to the general group of gums known as Bassorin gums. However, complete information regarding the chemical and physical properties of Karaya is not available in the literature. According to Pringsheim (3) the literature dealing with the gums and mucilages is very inaccurate and conflicting. Norman (4) states that no essential difference exists between gums and hemicelluloses; in both, hexose and pentose are linked with uronic acid. Solis-Cohen (5) gives arabin, bassorin and cerasin as the proximate principles of gums. Gums are chiefly pentosans. Many gums and vegetable mucilages, when dry, have the property of imbibing relatively large quantities of water. Porges (6), using a mucilage of the bassorin type, found that it imbibed about three times more water than linseed or psyllium seed, and five times as much as

agar. Parsons (7) and Klecker (8) reported that the bassorin they used absorbs slightly more than two times more water than agar.

We investigated the ability of Karaya to absorb water by comparing it with an equal quantity of agar. We found that when one gram of the Karaya† used in our study was added to 100 cc. of distilled water at room temperature (20° C.), it started to swell at once and within 20 to 30 minutes the beaker containing it could be inverted without spillage of the contents. Measurements showed that the Karaya gum will imbibe 96% of the water, and that an equal weight (1 gm.) of ground agar will imbibe 71% of the water. After 16 hours over sodium hydroxide in a vacuum desiccator, Karaya lost 13% of the imbibed water, and agar lost 54%. It is therefore evident that Karaya not only takes up more water than agar, but that it also holds it more firmly. It was these preliminary results that attracted our interest in Karaya as a bland substance which might be used to increase the bulk of the feces.

Fate of Karaya in the Gastro-Intestinal Canal. In view of the uncertainty as to whether hemicelluloses are digested in the gastro-intestinal tract, we deemed it advisable to determine whether Karaya is digested.

Feeding of measured amounts of unprocessed commercial Karaya gum (50-80 mesh) to ten dogs showed that the gum could be detected and most of it (95%) recovered from the feces by washing and selective filtration. The gum appeared as easily recognized masses of soft gelatinous composition for the most part separated from the fecal masses. All methods which we tried for the chemical isolation of the gum itself proved to be inaccurate.

Our efforts were then directed toward determining by chemical analyses of the dried feces whether any change in reducing substances occurred, and whether such a change might be used as an index of the disintegration of the gum in the intestine.

Six dogs were maintained on a standard diet and the stools were collected and analyzed for reducing substances. After a suitable control period Karaya was added to the diet for a five day test-period and then withdrawn for a second control period. The experiment was then repeated. It was found that the amount of reducing substances varied rather widely from day to day in both the control and test-periods. It was evident that if Karaya was disintegrated in the alimentary tract, it could not be detected by this method.

Williams and Olmsted (9) found such a very small quantity of copper reducing, sugar-like substances in the feces and such an abundance of volatile fatty acids that they decided to determine the volatile fatty acids quantitatively. They claim that the amount of the lower volatile

*From the Department of Physiology and Pharmacology, Northwestern University Medical School, Chicago.
Submitted November 29, 1937.

†A special preparation of Karaya called Mucara and supplied to us by John Wyeth & Brother, Incorporated, manufacturing chemists, Philadelphia, was used.

fatty acids gives an indication of the degree of laxation, and believe that bacterial enzymes hydrolyze cellulose and hemicelluloses into soluble products which either are absorbed as such or are immediately fermented to gases and fatty acids, such as acetic and butyric acid which stimulate the gut. In their experiments, however, the volatile fatty acids were not increased during the feeding of pentosans. In our hands the determination of the volatile fatty acids by Olmsted's (10) method did not give results of sufficient value to warrant its use as an index of laxation in dogs receiving Karaya. However, this failure to demonstrate an increase confirms Olmsted's (11) finding that pentosans do not increase the volatile fatty acids. According to some investigators, the digestibility of pentosans depends on the combination in which they occur. This may explain some of the differences in the results reported in the literature (12).

We fed Karaya to two totally depancreatized dogs who were maintained on a standard diet and subminimal doses of insulin. Also, the starvation D:N ratio was determined on two phloridized dogs, after which they were given Karaya. In neither case was the sugar loss in the urine changed significantly and the nitrogen elimination was not influenced in the phloridized dogs. Tests for urinary pentose were negative in these and other experiments.

If Karaya gum is disintegrated at all in the alimentary tract of the dog, its disintegration is so slight that it cannot be detected by any of the usual procedures. Of course, it is possible that the gum may be broken down into products other than those for which we have tested. However, as previously noted, we were able to recover approximately 95% of the ingested gum in the feces.

Facilities were not at our command to enable us to maintain human subjects on controlled diets. For this reason we made no attempt to determine reducing substances or volatile fatty acids in their feces. The urine of ten subjects taking Karaya was analyzed for reducing substances and pentose but no change or increase was found.

Effect of Bacillus Welchii and Yeast on Karaya. Bacteria are known (12, 13, 14, 15) which can attack both free pentose sugars and pentosans, but the presence of microorganisms which are able to attack hemicelluloses in the human intestinal tract have not been recognized. Gossman (16) used Van der Reis technic and showed that cellulose-fermenting bacteria can be isolated from all parts of the small intestine of man during life. We decided to determine whether *B. Welchii* could split Karaya. Kendall (17) has shown that this organism will utilize sugar in preference to protein whenever possible. Sugar-free infusion broth was inoculated with a typical strain of *B. Welchii* and after 48 hours incubation at 37° C. the amount of copper-reducing substance was determined by the method of Peterson and Fred (18).

The results showed that the strain of *B. Welchii* used was unable to utilize the carbohydrate fraction of Karaya.

Concomitantly with these various studies, Karaya was being given to a number of human subjects (vide infra). A few of them remarked that Karaya seemed to cause flatulence. Since we had not yet demonstrated an appreciable breakdown of the gum in the gastro-intestinal tract, we were at a loss to explain the cause of the flatulence.

Another effort was made to demonstrate that Karaya could be attacked. A suspension of Fleischman's yeast was mixed with Karaya and incubated at 37° C. with adequate controls. After three days, fermentation was observed in all tubes containing yeast suspension and Karaya, but none occurred in the control tubes. This experiment was repeated a number of times and two additional series of tests

were made after the Karaya had been sterilized with alcohol to rid it of any possible contaminants. The results were not modified.

Although the results of all the experiments show that Karaya is fermented slightly after from 2 to 3 days incubation with Fleischman's yeast, the amount of fermentation was too slight to permit a collection and an identification of the gas formed (19).

The interpretation of all results obtained in studies concerned with the possible degradation of cellulose or of hemicellulose must be tempered by the thought that results obtained on animals or with normal human subjects does not necessarily hold under abnormal states such as constipation, or under conditions of dietary peculiarities. Cowgill and Sullivan (20) suggested that the intestinal flora of the constipated individual might be peculiarly capable of decomposing plant roughage to a high degree. Cowgill and Anderson (21) found that the daily amount of roughage required to cause laxation was approximately 40 mg. per kg. of body weight greater in the individual with simple constipation than it was in the normal person.

Effect of Karaya on Nitrogen Utilization. Bastedo (22) quotes Whiteacre (23) as proving that bassorin paste reduces the assimilation of protein. An increase in the nitrogen in the stools on adding indigestible residue to the diet of animals and man has been observed by others (24-27). It has been shown by several investigators (28-31) that the fecal nitrogen is more closely related to the total bulk of the food consumed than its nitrogen content. Such effects have been attributed chiefly to the increased intestinal passage time, which decreases the assimilation of protein, but the amount of epithelium cast-off and a change in the flora must also be in part concerned.

The effect of indigestible residue on nitrogen excretion seemed quite important, since it is possible that Karaya might be taken consistently for long periods of time by some persons, particularly elderly persons with a simple type of constipation. Ten grams of Karaya were fed daily to five dogs for three months and no ill effects upon maintenance of weight or nutrition were observed. Then, metabolic studies were performed on five dogs in which the fecal nitrogen loss was determined before and after giving ten grams of Karaya with a basal diet of meat.

PROCEDURE

Five dogs were placed on a basal diet of 500 grams daily of whole ground beef heart. For three of the animals all feces were collected, weighed and then dried to a constant weight, for a five day period. A five day control period on beef heart alone was followed by a similar period during which 10 grams of Karaya were added to the diet. Carmine was used as a marker. Two of the animals were on the same regime but with the addition that a second control period followed withdrawal of the Karaya. The nitrogen of 500 mgm. samples was determined by the standard macro-Kjeldahl technic. No nitrogen could be found in the Karaya we used.

RESULTS

Dogs I and V showed an increase in nitrogen excretion while on Karaya of 38.4% and 35.7% respectively. Dogs II and IV showed decreases of 11% and 30% respectively. Dog III excreted the same amount of nitrogen on Karaya as during the control period. In two dogs feces were again collected after withdrawal of Karaya. An interval of three days was allowed to elapse between feeding of Karaya and the beginning of this last period of stool collection, in the

hope that all the Karaya would have been evacuated by that time. One of these animals excreted 50% more nitrogen than he did during the first control period and 10.5% more nitrogen than during the feeding of Karaya. Dog IV excreted 30% less nitrogen on Karaya than before it was given, but excreted 16.2% more nitrogen during the test period following Karaya than while taking Karaya.

Summarizing, the nitrogen excretion was unaffected by the addition of Karaya to the diet in one dog, the excretion was increased in two dogs and decreased in two dogs. Following the feeding of unprocessed commercial Karaya gum, nitrogen excretion was still further increased in one animal and decreased in another for a five day period. These results justify the conclusion that the bulk provided by 10 grams of the gum, Karaya, causes a variable effect on nitrogen excretion by way of the feces.

An increase in fecal nitrogen excretion would be anticipated if the passage of food through the gut were so rapid as to interfere with the assimilation of the protein in the diet. By using the carmine marker method, Karaya in 10 gram doses did not show a marked increase in their peristaltic rate in five dogs. However, the average number of defecations increased 60% with crude Karaya, and 53.9% of the human subjects (vide infra) had an increased number of stools. This seems to indicate that the time of passage through the alimentary tract is not increased, but the laxation rate, as defined by Cowgill and Anderson (21), is increased.

Our studies on 6 dogs with Mucara* containing Rhamnus Purshiana showed that passage through the alimentary tract is accelerated by from 4-8 hours. Rhamnus Purshiana belongs to the class of emodin cathartics which are known to increase the peristaltic movements of the colon, therefore, this acceleration was not unexpected.

It is our belief that bulk provided by Karaya may under some conditions influence food nitrogen assimilation, but that the amount which would be used for therapeutic purposes probably would not provide bulk of sufficient magnitude to interfere significantly with this important metabolic activity.

Effect of Karaya on Starch Digestion in the Dog.

Procedures: Six normal dogs were placed on the high starch diet used by Beazell, Schmidt and Ivy (32) which consists of 62% starch, 21% protein, 17% fat and 2 cc. of cod liver oil daily. One Kilogram of this diet was fed for several days, then all feces were collected for a five day period both before and while feeding 10 gm. of Karaya daily. Representative samples were analyzed for starch by the method devised by the above authors. Our technique varied only in that the feces were not washed with alcohol and ether to remove certain of the non-sugar reducing substances. This made our values somewhat high throughout the series, but since our interest lay in determining whether there was any interference with the digestion of starch when Karaya was given, the high values, per se, were not of concern to us.

The results show that with a high starch diet an increase in the amount of reducing substances (determined as starch) in the feces occurs on feeding Karaya, yet the increase is so small as to be practically negligible. Yet, the increased rate of passage of starch through the intestine may explain the increase in flatulence reported by a few of the human subjects. The lack of ptyalin in the saliva of the dog necessitates that all starch be digested in the intestine; therefore,

*This is the trade name under which the Karaya we used is marketed.

even such a slight increase in the intestinal peristaltic rate as might occur on the addition of Karaya might be just sufficient to pass the food through the small intestine before the enzymes could completely attack the starch.

Effect of Karaya on Vitamin A Utilization. A series of rat experiments were conducted to determine whether Karaya exerted a deleterious effect upon vitamin A utilization.

Procedure: Group I. Twenty-nine female albino rats 18-21 days old were placed on a basic vitamin-free diet supplemented with four drops of cod liver oil and 400 mg. of Brewer's yeast (vitamin A free) daily. As soon as consistent weight gains were recorded twenty-seven rats were started on a deficiency regime by substituting viosterol for the cod liver oil. The two remaining rats were maintained as controls. At the beginning of the observation period the average weight of the entire series was 27 grams, and the average weight at the start of the deficiency regime was 52 grams, or an average gain of 3 grams per day. As deficiency appeared alternate animals were placed in Groups A and B. Our criteria for vitamin A deficiency were ophthalmia and declining weight. However, we placed more reliance upon the appearance of ophthalmia for it had been our experience in a previous study in which the weight curve was taken as the sole criterion that many animals reached such an extreme degree of avitaminosis that it was impossible to bring them back to a healthy state. Steenbach and Coward (33) used the incidence of ophthalmia as an index of vitamin A deficiency.

The diet of Group A animals was supplemented with one gram of Karaya daily (provided as pills mixed with dextrin) and four drops of cod liver oil, and the rate of return to a healthy state was recorded. The animals in Group B were on the same regime as the animals in Group A except that no Karaya was given.

An average difference of only 4 days occurred in the time required to observe deficiency signs in the group receiving and the group not receiving Karaya. The time required for recovery from vitamin deficiency was also quite close in the two groups (Group A—17.6 days; Group B—19.8 days). No other differences were noted between the groups. Examination of the intestine of twelve of the rats (6 of which had been fed Karaya and 6 had not) exhibited no gross differences or abnormalities at the end of the experiment which lasted ninety-one days.

Group II. Seventeen female albino rats of an average weight of 33 grams were separated into Groups II (a) and II (b) consisting of nine control and eight test animals respectively. These animals were fed a standard diet complete in all respects. The diet of Group II (b) was supplemented with one gram of Karaya daily. All animals were weighed and observed twice weekly for sixty days.

The nine control animals gained an average of 181 grams each and the eight test animals fed Karaya gained an average of 183 grams. All maintained normal healthy coats.

It appears from the results of these experiments that relatively large amounts of Karaya fed continuously to young albino rats neither interferes with their normal growth, nor delays or prevents recovery from an induced vitamin A deficiency.

Effect of Karaya on the Feces of Normal Dogs. Since we were primarily interested in the value of Karaya as a laxative substance, we determined whether it was a truly bland material which would only increase the bulk and moisture content of the feces, and increase the number of stools either by distending the bowel or

by chemical stimulation. The literature contains no note regarding its possible irritant qualities; in fact there is no literature bearing on the medicinal use of Karaya.

Experimental procedure: Eight normal dogs were maintained on an adequate basal diet which caused an average of one normal defecation daily. The animals were fed daily at 8 a. m. Large water jars were kept in the cages. Total feces were collected for five-day periods, care being taken to avoid drying before the weight could be ascertained. The total output was weighed then dried in a hot air oven at 90-100° C. and reweighed as soon as a constant weight was reached. The difference between the first and the final weights was taken to represent the moisture content. Following a control period 5 grams of unprocessed commercial Karaya gum previously swelled in 100 cc. of distilled water were added to the daily diet for seven days. This was followed by three days of basal diet again, then seven days with test material added to the diet. The last five days of this period represented the actual test period. This procedure of three days between the control and test periods was followed throughout the study. The observations recorded upon the daily feces were (1) number of defecations, (2) character, (3) total weight, (4) final weight, (5) moisture (obtained by calculation).

Number of Defecations: The average normal daily number of defecations was one. Feeding 5 grams of unprocessed Karaya daily caused the average to increase to 1.6 (extremes 1-2.4); Mucara caused an increase to 2.2; Mucara with cascara produced an average of 1.6 (extremes 1.4-2.0); Mucilose raised the number to 1.4 (extremes 1.0-2.0).

Character of the Feces: In all dogs unprocessed Karaya caused the feces to soften, but rarely produced other than a poorly formed stool. Mucara softened the stools considerably more and not infrequently produced a formless mass. Mucara prepared with cascara showed approximately the same changes with the exception that there was possibly less tendency toward a formed stool. Mucilose also softened the stool, but it made the feces so gummy that the particles of feces adhered firmly to the weighing dishes. Agar caused some softening but definitely less than the other substances studied.

Total Bulk: The changes which occurred in the total bulk of the feces during the various test periods is interesting. Mucara increased the bulk most with an average for all dogs of 164.55%; Mucara with Cascara was next with an increase of 88.16%; Agar with an increase of 58.06%; Karaya with an increase of 52.25%; Mucilose with an increase of 48.93%.

These values assume more interest when compared with the changes in moisture content. Mucara caused an increase, average for all dogs, of 184.85%; Mucara with cascara increase of 101.85%; Karaya increase of 64.23%; Mucilose increase of 54.11%; Agar increase of 43.15%.

The variations observed in the order of values cannot be explained by the evidence at hand. Many factors should be considered, such as the effect of the substances on bacterial flora, excretion of lipids by the gut, their effect on absorption, their particle size, the water imbibed and their degradation in the alimentary canal.

Finally, an attempt was made to determine whether Karaya fed over a long period of time was irritating or lost its effect. After the usual control period of five days three dogs were fed unprocessed Karaya for thirty consecutive days. The stools were collected for

the five days immediately after termination of the feeding of Karaya. In all dogs the average daily grams of bulk were increased as was also the daily moisture content. The proportion of moisture to bulk also increased in all three dogs. Three weeks after discontinuing Karaya another control collection was made. Two of the three dogs had virtually returned to the original level. The values for the third dog had decreased from those obtained immediately after the Karaya but had not reached the original control level. This suggests that the action of Karaya might persist for a short time after discontinuance of the dose.

Cowgill and Anderson (21) found that normal men who changed suddenly from a high level of fiber intake to a low one showed a "hang-over" effect for several days. It seems that this increase following the feeding of Karaya must be other than a hang-over from the bulk provided by Karaya since the time elapsed (three weeks in 3 dogs) was long and the diet of the animals had been shown to be bulky enough to produce a daily stool, thereby excluding the lagging behind of the gum. This "after effect" will be discussed later under the human studies.

EFFECT OF KARAYA ON HUMAN SUBJECTS

Karaya was administered in the form of granules under the trade name of "Mucara," to 89 graduate and medical students, nurses and social workers (46 were female; 43 were male). Each subject kept an accurate account of all food and fluids taken for seven days. This diet was then repeated on the same days of the following week with the addition of one heaping teaspoonful of Mucara taken once daily after the evening meal (9 gms. Mucara = approximately 7 gm. Karaya). All stools were collected for the first five days of the first week and analyzed for bulk, moisture and character to provide a control period. The Mucara was started on the sixth day and was taken daily for four weeks. Stools were collected again on the 8th, 9th, 10th, 11th and 12th days to represent the test period. In a few instances where no effect from Mucara was noticed during the test period stools were again collected during the last five days of the month during which the Mucara was taken. Subjects were instructed to note any subjective sensations which developed while taking Mucara, but were given no idea as to any specific information which would be desired later.

The criteria upon which we based our opinion as to whether the desired laxative action was obtained concurred in the main with those laid down by Cowgill and Anderson (21) namely: (1) The subjective impressions of the person as to completeness and satisfactory character of the defecation. (2) The amount of intestinal contents evacuated under test conditions. (3) Water content of the stools. (4) Time of passage of material through the alimentary tract. (5) Number of defecations in a unit of time (laxation rate). (6) Amount of indigestible matter in the stool and the relation of this to the quantity ingested. The voluminous data obtained cannot be given in detail hence where ever possible the figures have been averaged or condensed so as to give the clearest picture of the changes which were apparent.

Sixty-six or 74.1% of the 89 subjects whose stools were analyzed reported the existence of a normal habit. For the sake of uniformity we have interpreted this to mean an average of about one stool daily from week to week, (in a few instances this would mean one stool

every third or fourth day). A few of the subjects reported 2 to 3 stools daily, but if this were their customary habit over long periods of time, and if the stools were soft, not excessively dry, well formed, and not preceded by, nor accompanied by discomfort, and there were none of those symptoms so frequently attributed to "autointoxication," we considered the individual to have a normal habit. Twenty-three or 25.8% reported constipation as their usual state. We interpreted this as marked irregularities of habit, poorly formed fecal masses, often scybalous, inspissated, accompanied by straining and discomfort and those symptoms so often attributed to "autointoxication." Many of these constipated individuals considered it necessary to use enemas or cathartic drugs frequently. Most of them had consulted physicians for constipation.

Bulk Production: Thirty-six or 40.4% of the total of 89 subjects reported that they were aware of an increase in the bulk of the stools while taking Mucara. This is interesting when one considers that by actual weight of the stools we found that 72 of the 89 (81%) showed an increase in bulk during the first five days on Mucara which ranged from a minimum increase for the five days of 15 grams or 2.4% up to 922 grams or 293.6%. Two other persons, who had a decreased bulk during the first five days, showed an increase during the last five days of the month. Eight subjects showed a decrease in bulk for the first five days on Mucara which ranged from 14 grams or 4.2% to 426 grams or 77%. Seven of these had an increase in bulk when they took Mucara with cascara.

Fifty-seven or 86.3% of the 66 individuals with normal habit obtained an increase in bulk and/or moisture with plain Mucara. Five or 7.6% of those with normal habit showed a decrease in bulk and moisture.

Fifteen of the twenty-three constipated subjects showed an increase in bulk and/or moisture with Mucara. Surprisingly, eight of these had a decreased bulk and moisture. Subjectively, the constipation was relieved in nineteen of the twenty-three subjects who reported constipation.

Moisture Changes: Sixty-seven or 75.2% of the total subjects reported increased softness of the stools while taking Mucara. Actually 75 or 84.2% exhibited increase in moisture during the first five days on Mucara. The increases ranged from 29 grams or 1.2% to 517 grams or 267%. One subject showed an increase in moisture only during the last 5 days of the experimental test period.

Eight of the total, during the first five days, showed a minimum moisture decrease of 18 grams (4.7%), to a maximum decrease of 374 grams (67.9%). Five of these acquired increased moisture when the cascara mixture was given in place of plain Mucara.

Number of Defecations: Forty-eight or 53.9% of the total showed an increase in the number of stools passed over a five day period. Twenty-eight increased by 1; 12 by 2; 4 by 3, and 4 by 4 stools. Only 12 or 13.4% of the total subjects were aware of any change in the number of stools passed over the control period; the records gave the actual increase. Fourteen or 15.7% of the total had a decreased number of stools. Eight were decreased by 1; 3 by 2; 2 by 3, and 1 by 4 during the five day period.

Subjective Impressions: Thirty-eight or 42.7% had increased consciousness of the call to defecate. Twenty or 22.4% claimed that Mucara produced a more satis-

factory and complete defecation. Six or 6.7% were less satisfied because of the soft character of the stools. Two or 2.4% remarked that the stools were firmer and drier and more difficult of passage. (Both actually had a decreased bulk and moisture). Seven or 7.8% complained of some abdominal discomfort associated with distension shortly after taking Mucara. Three or 3.4% complained of mild abdominal cramps while taking the Mucara. One subject complained that by the end of the third week on Mucara the stools were so soft as to be irritating on passage. Six or 6.7% reported that they were thirsty as long as they took Mucara daily. Four or 4.7% reported that the constipation which they customarily had in relation to the menstrual period was absent while taking Mucara regularly. Ten or 11.2% remarked on the malodor of the stools. Thirteen or 14.5% reported that the laxative effect of Mucara lasted for from 36 hours to several days (one reported several weeks) after it was no longer taken. Four or 4.5% reported either no stools or hard stools for from one to three days after stopping Mucara. One subject had a decreased urge to defecate for 10 days after starting Mucara (bulk and moisture were both decreased in this subject). One subject reported that his *Acne Vulgaris* disappeared while he was taking Mucara daily and that it returned within one week after stopping. No previous dermatologic or dietary therapy of any type had ever influenced his *Acne*, even yeast! One subject required mineral oil frequently because of painful hemorrhoids; occasional doses of Mucara replaced the need for mineral oil.

Flatulence: Fifteen or 22.7% of the sixty-six with normal habit were not aware of flatulence before this experiment but developed it while taking the Mucara. Twenty-one or 31.8% usually had flatulence and also had it while on the Mucara. Nine of these thought there was an increase in the degree of flatulence; 10 had less and 2 thought it remained about the same. Thirty-two or 48.2% of those with normal habit either had no flatulence before or after starting Mucara or else noted no change from their customary state. Twenty-two or 23.6% of the 89 subjects became aware of flatulence while taking Mucara whereas they considered themselves free of it before.

MUCARA WITH CASCARA

Nine individuals who failed to respond to plain Mucara were studied, with the same dose of Mucara with cascara. Four of these acquired an increased number of stools; 1 by 1; 1 by 2, and 2 by 3. Seven had an increase in bulk and moisture; one of these experienced drastic purging with this preparation. One had decreased bulk but increased moisture and 1 showed a decrease in both bulk and moisture.

SPECIAL EXPERIMENTAL SUBJECTS

Twelve patients were given Mucara without an analysis of the stools being made. The tabulation which follows is self-explanatory:

Two subjects not studied quantitatively received no relief from their constipation with plain Mucara, but were kept comfortable by a daily dose of Mucara containing cascara. One subject was aware of no change when the cascara mixture was substituted for the plain Mucara. One subject who had partial ileocecal obstruction due to adhesions remained entirely free from constipation as long as she took one daily dose of plain Mucara. One subject who "needed" enemas every third day in order to have a

bowel movement obtained no relief with either plain, or Mucara with cascara. One subject with duodenal ulcer who has taken Mucilose regularly, prefers Mucara with cascara, but she obtained no relief from the plain Mucara. Six subjects with simple constipation who asked to try Mucara have come back repeatedly for more. Previous medication of various types which they used were never as satisfactory as Mucara, they reported.

DISCUSSION

The discussion will be limited to those factors which are most concerned with the laxative properties of Karaya. The criteria upon which this evaluation is made have been previously referred to. In this connection the important work of Olmsted and Williams (15) should be mentioned. They based their evaluation upon two criteria: (a) the impressions of the subject as to whether or not the bowel movements were satisfactory, (b) the weight of the feces over and above the weight of the residue recovered in the feces. Due to our inability to feed our subjects quantitatively prepared diets, we were unable to determine the residue values for the diets.

The majority of our subjects reported a normal bowel habit. We were glad that this partition happened to occur for we knew from preliminary tests that Karaya was of value in constipation, but we had no knowledge of other properties it might possess. The use of Karaya by a group of normal persons should readily divulge any peculiarities of the substance.

An increase in bulk was the most consistent change noted in the experimental subjects. Williams and Olmsted (15) have shown that the hemicelluloses are more efficacious in increasing the bulk of the stool than are the cellulose or lignin fractions of indigestible residues. This effect of hemicellulose is amply demonstrated by our studies with Karaya. We found that the effect on bulk was proportional to the moisture in the majority of the subjects. The increase in bulk and moisture bore no relation to the quantity of bulk fed nor to the amount of water which could be absorbed by the given amount of gum, therefore, some less direct factor must also be concerned in the production of bulk. Whether this is due to a simple washing down of less fully digested food particles, protein for example, or whether due to increased glandular activity with resultant increase in cast off solids, we are unable to say.

The conditioning of the defecation reflex which occurs in so many human beings prevents the use of the record of the number of defecations per unit of time as an accurate criterion of laxation in Man. Over half of our human subjects gave evidence of an increase in the number of stools which we consider of definite significance in view of the fact that the same preparation more than doubled the number of defecations in the dogs under experimental conditions.

Although slightly less than half of the subjects had an increased urge to defecate, none of them reported this an undesirable feature. Hines, Lueth and Ivy (34) have demonstrated the marked variability in sensitivity to pressure within the rectum among human beings so that quantitative figures cannot be considered highly important on this point. It is worth mentioning that the increased urge did not appear to be caused by irritation other than that produced by distension, although here again proof is difficult.

About one-fourth of the subjects volunteered that Mucara produced a more completely satisfying defeca-

tion. When directly questioned on this point many others readily admitted that this was also their experience. We did not wish to include answers that were influenced, therefore we did not add these to the reports voluntarily made.

We see no adequate reason why the six subjects should have noticed increased thirst while taking Mucara. Two of these admitted that customarily they drank less than three glasses of fluids daily. One of the subjects drank six glasses daily at our request and reported that as long as she remembered to take that amount of fluid she was not thirsty and the stools were softer.

The failure to defecate for a few days after withdrawal of Mucara which occurred in four can be readily explained on the basis of sudden reduction in bulk.

The complaint of abdominal discomfort and mild cramps which occurred in a few subjects shortly after taking the Mucara is difficult to explain. How large a part psychic reaction plays when one knows that he has ingested a substance which swells we do not know. Tost (35) claimed that bassorin swells only very slightly in acid gastric juice. We added one-half gram of Karaya to 10 cc. of acid fasting gastric juice and found that it swelled to about the same extent as did one-half gram of Karaya in distilled water, but that the rate at which the Karaya swelled in gastric juice was about half that in the water. The recent report (36) of esophageal obstruction from another type of hygroscopic laxative should be borne in mind only if extremely large doses are given. The small size of the Karaya particles used in preparing Mucara tends to eliminate any such sudden swelling as may occur with differently processed material.

The malodor of the stools reported by some of the subjects might be associated with the liberation of certain gases if degradation of the gum occurs. We observed the feces particularly for gross evidence of fermentation because Bastedo and others have reported that bassorin stools are fermentative. It is thought that the fermentative stool might be due to the fact that the gums carry down undigested food.

Williams and Olmsted (15) state that the passage of flatus is as normal as the passage of feces, for the carbon dioxide and hydrogen passed are the normal excretory products of bacterial fermentation. In our interviews with subjects it was almost impossible to obtain accurate evaluation of the facts for when pressed, nearly all acknowledged the passage of occasional flatus which they themselves considered normal. We tried to base our data, therefore, on any symptomatic change in the degree of flatulence but here again the focusing of the attention on a symptom made it difficult to draw conclusions. We believe that there was a definite tendency toward increased flatulence on Mucara in 24.7 per cent of the subjects. However, with very few exceptions those who reported the greatest degree of flatulence remarked that it was never so annoying as to cause them to wish to discontinue the experiment.

The "after effect" of bulk has been partially discussed in the section on studies on the dog. From our clinical observations we believe that while part of the effect might result from the retention of gum in the gastro-intestinal tract, another factor is important. That is, the tendency for the individual to pay more attention to his habit, and the greater ease with which

a normal habit can be established when the stool is soft and bulky. Many of our subjects remarked that while taking Mucara the urge to defecate was more likely to come at their ordinary "stool time." We believe that one of the most important factors in the causation of constipation is the lack of a strong urge at the time of the day when defecation is most physiologic, namely, after breakfast. If the bulk is sufficient to initiate a definite urge, and the stool is soft and easy of passage one is more apt to heed the "call." It is largely because of this ability of Karaya to provide bland bulk and moisture that we consider the gum a valuable adjunct for the management of simple constipation.

The failure to increase the bulk and moisture of eight constipated subjects might be due to the peculiar situation described by Cowgill and Anderson (21) when they found that the roughage requirement of the constipated person was definitely in excess of the non-constipated. Further study is needed to clarify this observation.

The "hang-over" effect of Mucara has an important clinical application. We found that a few of the constipated patients studied had to take Mucara daily at first in order to achieve a regular, soft and satisfactory stool, but that as soon as this was established they were able to maintain it by taking the same dose of Mucara every second, third or fourth day. In fact, three previously constipated subjects who have continued to take Mucara of their own accord have found that they were able to take the doses an increasing number of days apart until finally a single dose of Mucara about once a week would maintain a normal habit.

Our studies with Mucara containing cascara were

brief and performed only on those persons who were unaffected by the plain compound. Its usefulness seems limited to such patients.

SUMMARY AND CONCLUSIONS

Karaya gum will absorb and hold a large quantity of water.

Karaya is not attacked by *B. Welehi* in vitro, but is slightly fermented by yeast.

Experimental evidence fails to prove that Karaya is appreciably disintegrated in the alimentary tract, for feeding Karaya to dogs does not increase the copper-reducing substances in the feces; does not increase the sugar excreted by depancreatized dogs; does not effect the D:N ratio in phloridzin diabetes. It does tend to increase fecal nitrogen excretion, although the effect is variable; it does not appreciably affect starch digestion in dogs receiving an excessively high starch diet; and does not inhibit the utilization of vitamin A in rats.

Karaya, in its unprocessed form, as well as in its processed form, Mucara, causes changes in the feces of dogs, such as increased number of defecations, increased bulk and moisture, and does not cause detectable irritation.

Mucara has been proved to be a useful, harmless laxative agent because it increased the bulk of the stool in 80.8 per cent of the human subjects studied; increased the moisture content in 75.2 per cent; increased the number of defecations in 53.9 per cent; and increased the urge to defecate in 42.7 per cent. It relieved constipation in 19 of 23 persons studied.

Mucara produces no harmful effects, nor is it habit-forming if taken over long periods of time. The evidence suggests its value as a regulator of bowel habit.

Mucara with added cascara is useful in those subjects who fail to respond to plain Mucara.

Intussusception in the Adult*

By

REUBEN FINKELSTEIN, M.D., F.A.C.P.

BROOKLYN, NEW YORK

INTUSSUSCEPTION is essentially an accident occurring most frequently during infancy and early childhood. Its recognition dates back many centuries. Hippocrates suggested treating the obstruction by inflation of the bowel from below (1). The first real descriptions of the condition were made by the anatomists of the 16th century who, however, associated it with volvulus from which it was separated by Peyer in 1677 (2). The first clinical observations were made during the 18th century notably by Kuhn in 1702, Velse in 1742, Hevin in 1768 and by John Hunter in 1789. The latter defined intussusception as "the passing of one part of the intestine into the other and commonly by the upper passing into the lower" (1). This almost 150 year old definition holds good today.

Meckel, Rokitsky and Cruveilhier reported cases with their treatment. It is not, however, until 1871 that we find the first record of abdominal section for intussusception by Mr. Jonathan Hutchinson (1). A review of the literature for the past 50 years reveals innumerable studies on intussusception mostly, however, in children under two years of age. Perrin and Lindsay (3) in a study of 400 cases found 78.5 per cent occurred in children under two years of age and only 4.5 per cent in patients over 14 years of age. According to Hinton (4) 95 per cent of all acute intussusceptions occur in children. Sullivan (5) and Dieulafoy (6) both stated that it is almost the only cause of obstruction in infants.

Lutzow and Holm (7) commented on the fact that intussusception is uncommon in Norway, only 29 cases having been recorded up to 1923. On the other hand it is quite common in England and Denmark. This is possibly due to the extensive use of calomel and castor oil in children in the latter countries.

Intussusception may be acute or chronic. The acute form is almost always found in children while in adults the chronic form is by far the more common. However, Mayo and Philip (8) in a study of 39 patients suffering from chronic intussusception reported one instance in a patient only ten years of age. Schlink also reported one case of intussusception lasting two months in a female child seven years of age, with recovery after operation. Elliot and Corscaden (9) in a very exhaustive study collected 300 cases from literature. They found that in St. Thomas Hospital, London, from 1875 to 1900 only 115 instances of intussusception were reported, of these only 10 per cent were in adults over 15 years of age. They also quoted Codman's report of 27 cases from the Massachusetts General Hospital prior to 1908 with only nine instances in adults. Davis (10) studied the records of St. Luke's and St. Mary's Hospitals in Duluth, Minnesota, and found that out of 113,351 patients admitted, intussusception was found in only 22 instances. This is at

the rate of one case of intussusception to about 5,000 admissions. Of these, only one patient was an adult 34 years of age.

In the Beth-El Hospital, 62,632 patients were admitted during the past 11 years with only six instances of intussusception, only one was an adult, our own case.

Invagination may occur in any portion of the bowel and true to Hunter's definition it is usually the upper segment that passes into the lower segment. Nevertheless, a number of instances of so called retrograde intussusception have been reported. In this condition the lower segment passes into the upper one.

The most common site for retrograde intussusception appears to be the gastro-enterostomy opening, where more or less of the jejunum is invaginated into the stomach. Becker (11) collected 38 cases from the literature, 23 females and 15 males, the youngest was 21 and the oldest 75 years of age. According to Sibley (12) the mortality of patients with retrograde intussusception appears to be high, about 50 per cent. The operative mortality was about 40 per cent but of those patients who were operated within 48 hours only 10

Fig. 1. Showing transverse and descending portions of the colon with a tumor mass occupying the transverse portion, spasm in the presplenic region and absence of ascending portion of the colon.

*From the Gastro-Intestinal Department, Beth-El Hospital, Brooklyn, N. Y.

Submitted November 17, 1937.

per cent died. Four patients who were not operated upon died.

Lewis (13) reported one case of retrograde intussusception in which the apex was the pelvic colon which was intussuscepted through the transverse and ascending portions of the colon reaching the cecum. Balfour (14) reported an instance of retrograde intussusception of the sigmoid due to tumors within the bowel with powerful antiperistaltic contractions in the proximal sigmoid. Intussusception may also occur during pregnancy. Chaffin (15) collected 11 cases from the literature since 1870.

As a rule only a single intussusception occurs. Although after reduction it may recur at the same site if not operated upon or at another site as reported by Blaxland (16). Multiple intussusceptions are rarely found in life but a number have been reported on post mortem examinations especially in the small intestine. They are probably caused by increased intestinal peristalsis during death agony (17).

The direct cause of intussusception is still not very well understood. Elliot and Corsecaden in their study found 33 1/3 per cent caused by tumors within the bowel; 60 per cent of these tumors were of a benign type and mostly found in the small intestine; 40 per cent were of a malignant variety and usually found in the large bowel especially in the proximal colon. Tumors found in the sigmoid and rectum were usually of a benign character. In 1936 Christopher (18) gathered from literature 43 more cases of intussusception due to benign tumors and 16 cases due to malignant tumors. Other causes are Meckel's diverticulum, the appendix and various forms of intestinal ulcers. An interesting case of intussusception in a

Fig. 3. Showing the transverse and descending portion of the colon filled with air and the tumor mass being pushed backward by the air pressure with attempted reduction of the intussusception.

patient suffering from ulcerative colitis was recently reported by Barger (19). Intussusceptions of the appendix alone have been reported (20).

The mechanics of intussusception consists of the telescoping of one portion of the tube into another. Where a malignant tumor or deep ulceration is present the adjacent intestinal wall becomes stiffened and the lumen narrowed. Peristaltic waves approaching this area are unable to pass through this stiffened segment but carry it forward into the distal bowel. Once an invagination has taken place peristaltic action pushes the intussusception forward as far as its attached mesentery will permit. In case of a polyp the mechanism appears to be somewhat different. The peristaltic wave pushes the polyp forward as it would any foreign body. Through its attached pedicle the polyp drags along the wall of the intestine and here also when the invagination takes place further intestinal peristalsis pushes the head forward. Where no polyps or tumors exist it is difficult to assign a definite reason for the intussusception. In such cases sudden hyperactivity in an intestine with an abnormally long mesentery or a defect in its wall has been considered the most likely cause.

Four types of intussusception have been described. 1. Ileocecal; the ileocecal valve and the adjacent ileum pass into the cecum and colon. 2. Ileocolic; the ileum alone prolapses through the ileocecal valve into the colon. 3. Colic; the large bowel is prolapsed into itself. 4. Enteric or ileal; the small bowel alone is involved.

The treatment is usually surgical. If seen and diagnosed very early, especially in children, attempts at reduction may be made by repeated enemas. Usually when the patient is seen by the physician adhesions have already formed, inflammation and edema are

Fig. 2. Showing the transverse and descending portions of the colon contrasted with air which outlines the tumor mass within the transverse colon.

Fig. 4. Showing the result of final operation with continuity of the ileum and transverse portion of the colon.

present and only through surgery is reduction possible. Because so many intussusceptions are due to tumors or polyps resection of the mass is the usual procedure.

REPORT OF CASE

The patient (Case No. 75748), a male, age 33 years, was admitted to the Beth-El Hospital February 12, 1936. He had been in good health until about six months previously when he noticed that he became dyspneic on exertion. At the same time he was disturbed by intermittent cramp like pains which radiated toward the back and both sides, usually accompanied by borborygmus and passing of flatus which seemed to relieve the cramps for the moment—the history of a partial intermittent obstruction. The cramp like pains appeared at irregular intervals and lasted from five to fifteen seconds. These symptoms increased in frequency until at the time of admission to the hospital they occurred almost every five minutes without any relation to meals. Alkalies and food seemed to have no effect on the symptoms. During the month before admission the patient had two or three loose bowel movements per day instead of the single normal bowel movement before the onset of the present condition. At times the loose bowel movements were tinged with blood. During the six months of illness the patient lost about thirty pounds in weight.

Because of his dyspnea and general weakness the patient consulted a physician who found nothing abnormal on physical examination, but a blood count revealed that the hemoglobin was only 40 per cent. A few months of treatment raised it to 60 per cent at which level it persisted until he was admitted to the hospital.

On admission, examination of the heart and lungs revealed no abnormal findings. Examination of the abdomen revealed a soft, elongated mass above the umbilicus quite tender and extending across the midline.

Laboratory Examinations: The urine showed no pathological changes with the exception of a few coarsely granular casts. Gastric Analysis disclosed a low acid value. The stool at the time of the examination showed no occult or gross blood.

Blood Count: Hemoglobin—60 per cent; RBC—4,400,000; WBC—18,350; polymorphonuclear—75 per cent; lymphocyte—23 per cent; monocyte—2 per cent.

X-ray of the Colon: Under the fluoroscope the opaque fluid flowed in freely from the rectum to the pre-splenic flexure region where a definite delay was noted lasting a few minutes due to spasm. After overcoming the spasm, the transverse colon filled rapidly, the flow stopping at the hepatic flexure which could not be visualized. Under the fluoroscope, the transverse colon was felt as a large, elongated, soft mass tender to palpation. The roentgenogram showed a dilated transverse colon fusiform in shape with an apparent contraction in the pre-splenic flexure region (Fig. 1). In the region of the hepatic flexure there was an irregular and defective filling. After evacuation, air was injected, another roentgenogram was taken which revealed a dilated proximal transverse colon with the outline of a tumor mass within the lumen of the dilated portion of the transverse colon (Fig. 2). Further distending the colon shows an attempt at reduction of the intussusception (Fig. 3).

Surgical Report by Dr. A. Iason: The abdomen was opened through an upper left rectus incision. A large mass was noted showing evidence of sub-acute and chronic inflammation which involved most of the transverse colon. On further inspection the cecum and appendix were found to be missing, and tracing the ileum it was found that the lower ileum, cecum and ascending colon were intussuscepted into the transverse colon as far as the splenic flexure. The intussusciptiens had lost part of its luster and showed a marked hypertrophy. The apex of the intussusceptum, at about the splenic flexure, on palpation, gave the impression of a mass. There was edema and congestion of the mesentery of the transverse colon and a small amount of fluid present in the abdominal cavity.

The mass was reduced by careful pressure on the intussusciptiens distal to the head or apex of the intussusceptum, thereby forcing the entire intussusceptum out. Because of the induration and apparent lack of viability of the cecum and ascending colon, it was deemed advisable to remove this portion of bowel, including the lower ileum. This was accomplished by a multiple-stage procedure. The lower six inches of ileum and the entire ascending colon were

Fig. 5. Photograph of resected cecum and portion of ascending colon. At A is the appendiceal opening; at B the ileo-cecal valve (transposed in opening the specimen); at C the distal end of the cecum; and at D the tumor mass.

brought out into the wound in the manner of a Mikulicz operation.

About four days later the exteriorized bowel was removed. Ten days after that a spur clamp was applied, obliterating the wall between the limbs of the bowel. The patient's recovery was uneventful and he was discharged in the fourth week with a single-barrel ileo-cecal fistula.

The patient was re-admitted into the hospital two months later when an attempted but unsuccessful closure was made. He was discharged then to allow a wound infection to clear up. A spur clamp had been re-applied to obliterate the remaining inch of spur between the ileum and colon and about nine months after the first stage the patient was re-admitted to the hospital. After a few days of pre-operative care, the continuity of the bowel was re-established as a final stage Mikulicz procedure. Practically primary union resulted (Fig. 4).

PATHOLOGICAL REPORT*

Macroscopic Description: The specimen as delivered to the laboratory consists of a piece of resected cecum with the appendix and ascending colon measuring when opened 15 cm. in length and 11 cm. in width. Two cm. from the blind end of the cecum at the level of the ileocecal valve, the wall is occupied by an annular tumor measuring 8 cm. in length and 4 cm. in width. The surface is eroded, the base friable. The edges are heaped up and hemorrhagic. A dense mass of inflammatory tissue is adherent to the serosa. Grossly no involved lymphnodes are recognized (Fig. 5).

Microscopic Description: Sections through the gross tumor are composed of huge irregular tubular glands lined by one or more layers of columnar epithelial cells with large irregularly placed hyperchromatic nuclei frequently containing considerable amounts of mucus. These glands extend deeply into the muscularis and in the subserosa where the mucoid character becomes predominant so that in places the glands are replaced by huge cystically dilated mucoid containing spaces in which bits of the lining epithelium are present. Surrounding the glands both on the surface and in the depths is a rather pronounced fibrosis and lymphocytic infiltration. There is no apparent penetration of glands into the vascular or lymphatic spaces.

Sections of the gut proximal to the tumor show a marked

fibrosis of the mucosal stroma, in places forming shallow papillae covered by a somewhat hypertrophied but regular and unicellular epithelial layer. Immediately contiguous to the neoplasm there is a pronounced hyperplasia and hypertrophy of the mucosal glands and a marked increase in mucus both within the cells and within the gland lumens so that here and there mucus containing cyst-like spaces are present; these are lined by regular epithelium. This picture is also present in the appendix where a considerable lymphocytic and some polynuclear leucocytic infiltration is present in all the layers more particularly in the fibrosed mucosal stroma. In the sections taken from the appendix, the ileum and tumor itself there is a pronounced hyperplasia of the subendothelial connective tissue of the arteries, and to a lesser extent the veins. Frequently complete obliteration is noted as a result of this hyperplastic tissue or by fibroblasts which invade the bland thrombus in the vessels which generally show some degree of re-vascularization.

Sections of the cecum and colon distal to the neoplasm show only a moderate lymphocytic infiltration of the submucosa and muscularis. All the sections show the serosa covered by a fibrinous exudate.

Diagnosis: Primary gelatinous adeno-carcinoma of the cecum, with (obstructive) hypertrophy and hyperplasia of ileal and appendiceal walls.

SUMMARY

1. The literature on intussusception in the adult is reviewed.

2. It is shown that intussusception does not occur frequently in the adult and when it does occur it is usually chronic.

3. Intussusception usually follows Hunter's Law, "The upper segment invaginates into the lower segment," nevertheless a number of retrograde intussusceptions have been reported.

4. The probable causes and mechanics of intussusception are discussed.

5. A case of chronic intussusception in a male 35 years of age is fully reported including the clinical investigation, the surgical procedure and the pathological report.

ABRAHAM, MARGERY AND WIDDOWSON, ELSIE.

Modern Dietary Treatment. (William Wood and Company, Baltimore, Md., 1937).

This book of 328 pages is like a grain of wheat from which the chaff has been removed. It is short and readable.

The opening two chapters are devoted to the principles of nutrition, dealing with carbohydrates, fats, proteins, minerals, vitamins, roughage, alcohol and water, and giving a table of the main sources of the various food essentials.

The next eight chapters are devoted

to a discussion of high and low calorie diets; invalid diets, including fevers, convalescence, fractures and heart disease; diseases of the alimentary system, including peptic ulcer, gall bladder, liver, pancreatic and colon disease; diabetes; kidney disease; metabolism; B. coli infections; epilepsy and rheumatism; and diets for Jewish patients. These various subjects are by no means given adequate or comprehensive treatment, presumably because the authors are not physicians. Although these chapters might be criticized for such primer-book presentation, they may suffice for the purposes for which this book was designed.

The last four chapters, in volume representing more than half of the book, are composed of food tables, diets and recipes, and rather comprehensive tables of the chemical composition of foods.

The extensive bibliography attests the amount of work expended in the concise compilation of this book. The index is well prepared.

Written and published in England some of the diets would be impractical in certain portions of the United States, but enough material can be found in the tables to make this a useful hand book of dietary treatment.

and B. G. Gledhill.

BRUGER, M. AND FITZ, FRED.

Experimental Atherosclerosis: I. Effect of Prolonged Administration of the Thyrotropic Factor of the Anterior Lobe of the Pituitary on Experimental Atherosclerosis in Rabbits.

The authors refer to the original observation of Murata and Katoaka (1917) that the feeding of iodine prevented the deposition of cholesterol in the arterial walls, and that thyroidectomy (Turner and Khayat, 1933) abolished this protective action.

The present study was undertaken to determine what effect the pituitary gland, through its elaboration of the thyrotropic factor, exerts on experimental atherosclerosis in rabbits. Six groups of young rabbits were studied as follows: first, controls; second, rabbits to which 0.5 cc. thyrotropic factor only was administered 6 days per week; third, to which 1 gm. cholesterol 3 times per week and 1 cc. normal salt solution 6 times per week were administered; fourth, to which 1 gm. cholesterol 3 times per week and 0.25 cc. thyrotropic factor 6 times per week were administered; fifth, to which 1 gm. cholesterol 3 times per week and 1 cc. thyrotropic factor twice a week were administered,

Do Canned Strained Foods Supply Infants With Significant Amounts of Vitamin A?

A two-ounce feeding of Gerber's Strained Spinach supplies 6000 international units of Vitamin A. This is double the standard allowance of vitamin A per infant per day, which lies between 2000 and 3000 international units (1, page 20) (2)

Strained carrots give, per two ounces, 3600 international units; apricot and apple sauce, 1700 international units. Strained green beans, peas, or vegetable soup con-

tain 650 or more international units of vitamin A; even prunes with only 350 units in two ounces contain over one-tenth of the infant's total daily requirement. (3)

Therefore, practically all of Gerber's Strained Foods are excellent sources of vitamin A. For maximum health, or well being, an abundance of vitamin A, several times the minimum requirement, appears to be desirable.

It is generally agreed that vitamin A or carotene can be rapidly destroyed by heat if oxygen or oxidizing agents are present (1), but that heat is not destructive in the absence of oxygen. Gerber processes strained foods in a closed system with steam under pressure to exhaust cell oxygen and remove air. Storage after canning in tin cans has been shown to have no effect on the nutritive elements. (4)

and sixth, to which 1 gm. cholesterol 3 times per week and 1 cc. thyrotropic factor 6 times per week were administered. The animals were treated thus for about 120 days each before being killed for study. The entire aorta was then removed and the total cholesterol and ester cholesterol determined by standard methods. Throughout the period of observation the whole blood cholesterol was determined every 15 to 17 days in each rabbit.

The results showed that the continued administration of the thyrotropic factor alone over a protracted period of time exerts little influence on the cholesterol content of the aorta. When cholesterol and normal salt solution are administered there is an increased cholesterol content found in the vessel wall without much change in the ratio of ester to free cholesterol content. When, however, cholesterol and thyrotropic factor are given together to rabbits over a prolonged period, there appears in many instances a greater deposition of cholesterol in the aorta and the ratio of ester to free cholesterol is frequently elevated.

In the main the authors found that the cholesterol content of the aorta appeared to vary directly with the average concentration of cholesterol in the blood. There were 21 rabbits used in the entire study and this conclusion is based upon this number of observations. Those rabbits which received the thyrotropic factor in addition to cholesterol showed, as a rule, a greater deposition of cholesterol in the aorta than in those rabbits given cholesterol alone, but the average cholesterol content of the blood in each group remained about the same. This observation that in experimental rabbits the extent of arteriosclerosis, as gauged by the cholesterol content of the aorta, varies directly with the degree of hypercholesteremia, is at variance with the findings of Lundé and Sperry who studied the lipid content of the aorta and the concentration of cholesterol in the blood serum of 123 healthy persons who met with violent death and in whom there was found no relation between the degree of atherosclerosis in the aorta and the concentration of the cholesterol present in the blood. (As the above variance in observations may be of fundamental importance in the final understanding of atherosclerosis in man, it would seem important that further and more extensive studies along the same lines be made. The influence of the thyrotropic factor used in the above experiments may have been primarily in the nature of an injury to the vessel wall which permitted a secondary deposition of the cholesterol—Reviewer).

PHELPS, KENNETH A.

The Early Treatment of Chemical Burns of the Esophagus. Jour. Lancet, 58:237-238, May, 1938.

Chemical erosion of the esophagus belongs in the class of serious and painful diseases. When a corrosive fluid is swallowed, necrosis of the mucous membrane occurs and the depth of the necrosis depends upon the concentration of the poison, and also upon the length of time it is in contact with the mucosa. As the necrotic tissue sloughs off, an ulcer forms and spasm occurs in an attempt to immobilize the ulcer and diminish pain. This stage of acute stenosis is reached in from 3 to 5 days,

while the resistance of the walls of the esophagus has not suffered. This is the time to start treatment without fear of perforation. If treatment is neglected, the opposing granulations grow, and produce a fold-like stenosis, which will increase the danger of perforation. The final stage is the replacement of the inflammatory infiltration by bands of scar tissue, resulting in stricture. Early treatment prevents this.

Salzer recommends the use of an elastic esophageal bougie, filled with lead shot, beginning on the second day, leaving the bougie in place a minute or two. The time is gradually increased on subsequent days to 30 minutes a day by the sixth day. The author has found

Zymenol

Yeast Enzymes in Oil Emulsion

INDICATED FOR SUMMER DIARRHEA (Intestinal Flu---Summer Colitis) CONTROL

Without constipating after effect.

Both putrefaction and excessive fermentation in the intestinal tract are checked by the catalytic action of Zymenol. Brewers Yeast Enzymes (without living, complete cells). Fecal mass becomes soft and bulky, less toxic and less irritating. Normal evacuation is restored by natural impulse without drugs, roughage, artificial bulk or agents preferably avoided. (No Phenolphthalein. No Casarea. No Purgative).

The more normal physiological action of Zymenol is demonstrated by its effectiveness in the stagnant as well as the irritable, unstable bowel.

Sugar-free, Ideal for Diabetics.

No Leakage. Less Expensive.

Well tolerated by all ages.

Only TEASPOON dosage

LOCKHART-MUMMERY, J. P.

The Causes of Hemorrhage from the Rectum. British Med. Jour., 1937-1938, May 7, 1938.

Bleeding from the rectum is a condition which is always of considerable concern to the patient and one which should be thoroughly investigated in

order to determine its cause and significance. Probably two-thirds of all cases of rectal bleeding are due to internal piles, and such a condition can generally be recognized by a simple examination of the rectum with a speculum. It is well to remember that the presence of internal piles does not exclude the possibility of a carcinoma higher up the bowel.

The next commonest cause of rectal bleeding is carcinoma. The diagnosis is, as a rule, readily established if a finger is passed well up into the rectum as probably 80 per cent of rectal growths occur within reach of the finger. Digital and sigmoidoscopic examination should be done before an X-ray is ordered. An

innocent adenoma will cause hemorrhage and it should be removed, as there is grave danger of it becoming malignant.

Hemorrhage due to peptic ulcer generally results in tarry stools due to partial digestion of the blood, but where the bleeding is copious or rapid and the bowels are not loaded the blood may be seen in the stools as bright fresh blood. A rare and obscure cause of rectal hemorrhage is a peptic ulcer in Meckel's diverticulum which is apt to occur in young persons. Another rare cause of rectal bleeding is an angioma of the rectum or sigmoid. Local injury must be remembered as a possible cause of bleeding from the rectum. Hemorrhagic or ulcerative colitis may cause rather serious bleeding but rarely serious enough to endanger life. Bleeding from the rectum may occur in persons with very high blood pressure, and may be profuse, and the pressure considerable reduced thereby.

Hemorrhage is a complication that occurs after operation upon the rectum in about one per cent of cases. The most common time for hemorrhage is about the eighth day after operation. The use of a small tube inserted in the rectum will usually stop small hemorrhage and will eliminate the possibility of concealed bleeding. In cases of persistent bleeding the rectum should be packed by means of a rubber tube with gauze wrapped around on end in figure of eight fashion to form a bulge, which is inserted through a speculum. The pack is anchored firmly in place by means of a safety pin and gauze around the part of the tube projecting from the rectum.

VON GLAHN, WILLIAM C., FLINN, FREDERICK R. AND KEIM, W. FRANKLIN, JR.

Effect of Certain Arsenates on the Liver. Arch. Path., 25:4-488, April, 1938.

The authors report a series of experiments on rabbits in which cirrhosis of the liver was produced by the continued administration of small amounts of arsenic in the food.

The experiments were undertaken because during a study of the effect of various diets on the liver of the rabbit in a series of ten rabbits fed on cabbage only pigment was found increased in the liver cells of most of the animals and in many of them large phagocytes containing pigment were present in the sinusoids. On repeating these experiments three times similar changes were not produced and the thought came to them that possibly the cabbage fed to the first series of rabbits might have been treated with one of the insecticides frequently employed for the spraying of fruit trees and vegetables. Lead arsenate, one of the commercial

Saline alkali buffers in an effervescent tablet

Medical authority recognizes the rationale of prescribing buffer salts normal to the body as a safe, effective means of securing alkalization.

Convenience as well as safety is represented in the effervescent tablet

Alka-Vess

HERE IS THE FORMULA:

Each tablet contains

Calcium Di-Hydrogen Phosphate . . .	3 grs.
Potassium Bicarbonate . . .	1 gr.
Magnesium Sulphate (dried) . . .	1 gr.
Sodium Chloride . . .	1 gr.
Citric Acid . . .	19 grs.
Sodium Bicarbonate . . .	31 grs.

Supplied in convenient tubes of 25 tablets

For the Aristocracy of Thought

Your highly valued Journal is made to order for the aristocracy of thought of the Medical Profession of America . . . it has become a habit with me, and I would not care to miss a single issue.

The AMERICAN JOURNAL OF DIGESTIVE DISEASES

Was NOT established as a *vade mecum*, a news magazine, a humorous monthly nor a fictional alleviation for the jaded nerves of busy doctors . . . Most readers by this time have divined this point of policy, and have come to know that, month by month, this periodical gives a cross section of current and modern gastro-

enterological thought. It sees most of the manuscripts in this specialty: it prints all of them that are suitable . . . BETTER articles will be printed only when BETTER articles are written. The reader may confidently believe that at present the best work in gastro-enterology finds its way into these pages . . . Another way of saying that the management of this JOURNAL is seeking to perfect a really worth-while Archive in a most important field.

It is the firm intention of the Editorial Council that the pages of this Journal shall be kept FULL of important matter, and entirely EMPTY of all matter that is irrelevant . . .

Readers feel today that an important contribution to American Medicine is being, and will be, made through the agency of the American Journal of Digestive Diseases . . .

I am an admirer and reader of your excellent magazine.

You cannot improve on the editorial content—it is and should be, an outlet for scientific thought.

Material and format are excellent. I enjoy it very much because the articles are scientific.

It is certainly a well edited Journal and anyone who subscribes to it certainly gets his money's worth.

Quality brevity, educational value, scientific dignity, good typography and singleness of purpose are making friends in increasingly large numbers.

No Other Special Medical Journal Ever Made the Subscription Showing in 4 Years That Has Been Accorded to the American Journal of Digestive Diseases

With only the numerically small American Gastro-enterological Association as a formal backer, this Journal has independently attracted a record group of constant readers.

WHY?

The reasons are obvious —

- One of the strongest Editorial groups in American Medical Journalism, realizing the void that existed in gastro-enterological literature, determined to make a special Journal that would meet very specific needs.
- The needs were for a journal that would collect and attract under one head the important contributions in this field, thus enabling the reader to learn what he wished without the inconvenience of looking through an extensive literature.

• This has been done . . . today our Editor receives countless manuscripts from the investigators of the U.S.A. . . . today numerous readers volunteer the fact that they have never made better investments than in the Volumes of the American Journal of Digestive Diseases.

Spend \$6.00 per year or \$10.000 for two years NOW.

Join the increasing Group of doctors, whose enthusiasm has made and is making history in American Medical Journalism.

products commonly used for this purpose, was bought in the open market and used in some of the animals. This product is 98 per cent lead arsenate. Cupric arsenate, another commercial product was also used; and, in order to control any changes that might result from the lead and the copper of these products, chemically pure sodium arsenate was fed in another series.

Besides rabbits, experiments were also conducted on rats and ferrets. A biopsy on the liver was performed on each animal some days before the experiment was started. Then as samples of cabbage to be fed were found to contain 4.32 mg. of arsenic per kilogram comparable amounts were added to all of the diets. Oral administration was employed, as this is the manner in which arsenates contaminating food products gain entrance to the body.

Three diets varying in the carbohydrate content were used: namely, hay and oats with forty-six rabbits; hay, oats, carrots and cabbage with eighteen rabbits; and white bread and potato was fed to twenty-six. Each series was divided into three groups, the animals of which were given copper arsenate, lead arsenate and sodium arsenate respectively.

The lesions in the liver resulting from the ingestion of the different arsenates were similar in all. As early as the third day necroses of liver cells were found. These necroses were sharply defined from the surrounding liver cells. The necrotic cells were swollen and pale staining, at times the cytoplasm was transparent and the nuclei fragmented or destroyed. They were most frequently situated near the portal areas, sometimes surrounded it completely; sometimes they extended from one portal area to another. At times small groups of intact liver cells were surrounded by necrotic areas. About the necrotic areas were many large phagocytic cells, many with multi-nuclei. Later the necrotic liver cells were removed and there remained a mass of delicate fibrillar material which appeared to be collapsed stroma, and into these areas at a still later period fibroblasts penetrated and caused definite scarring. The gross appearance of the livers was altered in many of the animals. Usually the organ was smaller than normal and the capsular surface irregular or pebbled. Jaundice was present in some. Glycogen was reduced in the liver cells. In brief the livers in rabbits living but 2 or 3 days showed as a rule necrosis of some of the cells. When the animals lived longer, that is, from a month to a year or more, most of the livers showed the presence of a true chronic cirrhosis. There were some exceptions.

The animals to which carrots and cabbage were added to the diet showed a lessened degree of necrosis of the liver cells and an earlier grade of cirrhotic change than found in the

livers of those rabbits fed on hay and oats only. In the twenty-six rabbits fed on white bread and potato, a minimal cirrhosis was found in only two animals. A few scattered hepatic necroses were found in but three. The phagocytic cells were less numerous and the deposition of pigment less marked. Considerable glycogen was found in the liver cells. It seemed evident that the presence of carbohydrate had protected the livers from damage. This observation corresponds to a similar observation in man by clinicians.

Fifty-one rats and fifteen ferrets were studied in a series in like manner. In no animals was there observed any necrosis of the liver cells or a single instance of cirrhosis. These experiments merely showed that so far as damage to the liver is concerned, these animals are more resistant to the effect of arsenates than are rabbits.

Under the controlled conditions of the experiments it may be concluded that the lesions in the liver are the direct result of the effect of the arsenates upon it; that the lead and copper

"Patients Do Not Tire
of the Delicious
Flavor" —

HORLICK'S
The Original
MALTED MILK

It is remarkable the many cases which are reported, where patients have been confined, even when exclusively, to a diet of Horlick's, and yet they continue to relish and enjoy its delicious flavor. And it is so easy to prepare — just add to water and mix quickly with egg beater, or other handy mixer.

On account of its low curd-tension, Horlick's is frequently more acceptable to the individual — more easy to digest. The malt flavor of Horlick's helps overcome the monotony often experienced in a plain milk diet, when Horlick's is mixed with water and even when mixed with milk.

Horlick's Malted Milk Tablets, natural and chocolate flavors, contain the same remarkably nourishing and digestible qualities as the powder form, and offer a pleasing and unusual variant to the liquid diet.

Samples and literature sent upon request on your physicians' prescription blank.

HORLICK'S

Wisconsin

from symptoms, a proctoscopic and digital examination showed marked narrowing of the rectal lumen due to rectal edema and hypertrophy of the wall. Autopsy, four months later, revealed an edema and true fibrosis of the wall. There was no evidence, gross or microscopic, of rectal malignancy.

Case II. A male, 72 years, also received two series of radiation for prostatic malignancy, with favorable effects, from May 22 to Dec. 4, 1935. In this case, rectal symptoms appeared soon, about two months after the start of

radiation. Fecal incontinence was present off and on until April 17, 1937, when symptoms of intestinal obstruction appeared. On rectal examination there was marked edema of the wall with narrowing of the lumen and a mass in the lumen, probably fecal. The patient failed to improve with local measures and a colostomy was performed. He died two hours after the operation. The observations at autopsy indicated that compression of the rectum by metastatic lesion was not sufficient in itself to produce complete

obstruction, but the edema and fibrosis of the rectal wall was quite a factor.

The intimate anatomical relationship of the rectum to the other pelvic organs accounts for its involvement when any of these organs is subjected to intensive radiation therapy.

Although in each of the above cases the malignant lesion had not been eradicated by the radiation and early death was inevitable, it is believed that the recognition of such rectal stenosis in certain other patients, in whom the primary lesion is under control, may lead to appropriate surgical therapy and be life saving.

It is important that the author has called attention to the occasional dangerous effects of over-radiation in numerous cases of intra-abdominal cancer. Although he has reported only two cases of stenosis of the rectum in his general discussion of the subject, he found in the literature that the frequent unhappy result occurs following radium treatment for carcinoma of the cervix. Of 18 cases treated by Everett, seven developed vesico-vaginal fistula and eleven bilateral ureteral stricture. The experiences of other authors also are quoted such as Bule and Malmgren, Newell and Crossen, Jones and Ferguson.

and Nathan M. Noble.

DRAINAGE OF THE ENTIRE BILIARY TREE

The Aim of Therapy in Biliary Tract Disease

Decholin--c. p. dehydrocholic (triketocholanic) acid--is of recognized merit in affections of the hepatobiliary mechanism. Acting directly upon the liver, it increases bile secretion as much as 200 per cent; at the same time, it markedly augments cholecystic evacuation. It is a means of establishing drainage from the *entire* biliary tree, thus aiding in the removal of inspissated, stagnant bile and nidi of infection, and

lessening the absorption of toxic metabolites. In the hands of many of America's outstanding internists Decholin is the medication of choice in chronic cholecystitis, hepatitis of toxic origin, non-calculous cholangitis, and biliary stasis. There is only one contraindication: complete obstruction of the common or the hepatic duct.

PORTIS, SIDNEY A.

Should We Operate On All Our Cases of Gall Bladder Disease? Radiologic Review and Miss. Valley Med. Jour., 60:90-93, May, 1938.

Since the introduction of the Graham-Cole test and the increasing skill of the surgeon in removing presumable disease of the gall bladder, more and more surgery has been done in recent years for bile tract disease. The author raises the question as to whether or not all this surgery is warranted, especially in cases of mildly diseased gall bladders.

Attention is called to possible errors in technique causing a non-visualization of the gall bladder. One of the most common sources of error is that many patients have a meal containing fat shortly before the dye is given by mouth. Another reason for non-visualization is that the liver may retain the dye and fail to secrete it, owing to disturbed liver function.

Patients who have gall stones, a markedly diseased gall bladder, or a non-visualized gall bladder should be operated upon unless contra-indications exist. Many patients, particularly those who have had mildly diseased gall bladders removed, complain of symptoms similar to those they had previous to operation. It has been shown that many of these patients suffer from acute spasm of the sphincter of Oddi with enlargement and distention of the common duct. The spasm is relieved by

Body CALCIUM Blood ALKALI

Quickly Restored *with* **C-G ALKALIZER** *Effervescent*

Each heaping teaspoonful of Emerson's C-G Alkalizer contains a substantial quantity of calcium gluconate, regarded as the most easily-assimilable form of calcium available today.

Unlike the harsh, earthy alkali compounds, C-G Alkalizer furnishes alkali salts to the blood with no damage to normal HCl of the stomach. A goodly quantity of pure sodium citrate in every dose provides *systemic alkalinity physiologically*. No danger of alkalosis. Digestion is aided, *not* harmed.

For a rich source of calcium and alkali for blood and tissues, turn to C-G Alkalizer — in pregnancy deficiencies and nausea, convalescence, diarrhea, common cold; la grippe and other febrile diseases; wherever acidosis strikes.

LOW COST — PALATABLE

C-G Alkalizer costs 25% to 35% less than other good alkalizers. Its snow-white granules make a zestful, effervescent drink.

some form of amyl nitrite or nitroglycerine.

Drastic chologogues should be omitted in the medical management of gall bladder patients. Hypomotility and stasis of the gall bladder is frequently seen in hypothyroid states and marked clinical improvement is often seen when adequate thyroid is given. It is believed that foci of infection may be a factor in gall bladder disease by setting up an allergic response in the gall bladder. Patients are frequently seen with gall bladder disease and an associated myocardial condition and an improvement of the myocardial condition has an associated improvement in the gall bladder picture.

Adequate pre-operative preparation is most important in attempting to lower the surgical mortality in patients with bile tract disease. The patient should be on a pre-operative diet for several days prior to operation and laboratory work should include the following—urinalysis, complete blood count, Wassermann and Kahn, bleeding and coagulation time, and blood chemistry to include non-protein nitrogen, blood sugar, icterus index, and albumin-globulin ratio. Suitable donors should be ready if transfusion becomes necessary. Patients whose albumin-

globulin ratio, icterus index, or cholesterol ester fraction of the total cholesterol are not within normal limits, are poor surgical risks.

Postoperatively gall bladder patients should have plenty of glucose, intravenous fluids, and carbon dioxide inhalations to expand local regions of atelectosis. The diet should be gradually increased to one similar to the pre-operative high-carbohydrate, low fat diet. There should be no urgency for surgery of the bile tract except in cases of suppurative cholecystitis or possible gangrene of the gall bladder.

Cases of gall bladder disease which are intractable to medical management, those that have gall stones, and those cases with associated pericholecystic disease should have surgical intervention. Those cases of functional disturbance, particularly the so-called cholesterosis of the gall bladder or "strawberry gall bladder" had better not be treated surgically, but medically, because these patients are as a rule most uncomfortable following surgical intervention.

Pre-operative and post-operative diets are outlined.

LOE, RALPH H.

Gastroscopic Examinations—A Review of 80 Cases. Northwest Med., 37:139-142, May, 1938.

Gastroscopy is a safe, relative painless procedure which gives a clear picture of the interior of the stomach. It is a valuable adjunct to use in clarifying questionable roentgen defects of the stomach. The accuracy of the findings depends upon the skill and ability of the examiner. The fault of misrepresentation rests upon the one making the examination and not on the instrument.

Gastroscopy is of value in determining whether an ulcer is benign or malignant. It may aid in determining the operability of a carcinoma of the stomach, and its usefulness may be enhanced in this respect by using it in conjunction with the peritoneoscope. Gastroscopy offers possibilities of definite diagnosis in the late sequelae of postoperative stomachs. It is supreme in the diagnosis of chronic inflammatory lesions such as the superficial, atrophic, and hypertrophic types of gastritis. This discussion is based on a review of eighty cases examined by the author.

QUICK, A. J.

The Nature of Bleeding in Jaundice. J. A. M. A., 110:1658, May 14, 1938.

The author presents experimental observations made on the coagulation of the blood which furnishes significant information on the nature of cholemic bleeding and offers practical suggestions for the management of jaundiced patients. He has developed a simple method for the determination of prothrombin. This is done by observing the clotting time of oxalated plasma when mixed with an excess of thromboplastin and an optimum amount of calcium. When the thromboplastin and calcium are constant the rate of coagulation depends on the concentration of prothrombin and is a direct means for determining this factor.

Prothrombin determinations were also made on both normal and abnormal individuals and it was found that in normal individuals it was constant. In hemophilic blood it was found to be quantitatively normal while in jaundiced patients it was found to be extremely low in some cases. This deficiency of prothrombin has been shown to bear a direct relationship to the severity of the bleeding. Therefore experimental reduction of prothrombin was brought about in three ways: first, by vitamin K deficiency, second, by a toxin (spoiled sweet clover hay), and third, by injury of the liver.

After it was found that any one of the aforementioned factors would produce a hemorrhagic tendency it was

OLEUM PERCOMORPHUM CAPSULES

for diets deficient in
VITAMINS A and D

Where there is an intolerance or an aversion to fats, such good sources of vitamin A as dairy products are studiously avoided by patients. Obesity, diabetic, pregnancy, and low-cholesterol diets especially tend to be deficient in vitamin A. Oleum Percomorphum Capsules offer a convenient and highly acceptable means of correcting this deficiency and also furnishing generous amounts of vitamin D. Each 10-drop capsule supplies not less than 13,300 A units and 1,850 D units (U.S.P.), the equivalent of more than 5 teaspoons of U.S.P. cod liver oil in natural vitamins.

TRICALSATE

DUOCHOL
(PLESSNER)

Duochol (Plessner) provides the hepatobiliary stimulation required in the management of chronic cholecystitis, toxic hepatitis, and stone-free cholangitis. Its contained highly purified bile salts (2 gr.) and sodium salicylate (2 gr.) increase bile secretion by the liver and augment gallbladder contraction. Stasis in the entire hepatobiliary tree is overcome, producing prompt relief and improvement. Duochol (Plessner) contains no drastic cathartics. Small quantities of stomachics and ext. cascara aid gastrointestinal activity. Sample and literature on request.

THE PAUL PLESSNER CO.
DETROIT • MICHIGAN

thought that bleeding in jaundiced patients might be due to a deficiency of vitamin K or liver destruction. These cases must be treated first by transfusion in order to bring about an immediate increase in the prothrombin and then by the administration of vitamin K in the form of powdered alfalfa leaf or an extract of it.

Francis D. Murphy, Milwaukee.

MCGREGOR, JOHN AND ROTHENBERG, MORRIS.

Congenital Absence of Portion of Small Intestine. Northwest Med., 37:124-126, May, 1938.

The authors report a case of congenital absence of a portion of the small intestine. An attempt was made to correct the condition surgically by a side to side anastomosis. The surgery was accomplished without difficulty but the patient died 14 hours after the operation.

The two segments of the intestine ended in blind pouches near the lower border of the liver. The mesenteries of both were free and terminated at the end of each pouch, thereby forming two free borders.

The incidence of the condition is not at all common. Various authors report its incidence to be from 1:20000 to 1:3150 births. Surgery is the only treatment and it is essential that dehydration and alkalosis be combatted both pre and post-operatively. The mortality is about 100%.

References are given to articles with excellent discussions on the possible etiology and classification of intestinal anomalies.

CARMICHAEL, JOHN L.

Hyperinsulinism Associated with Hypothyroidism: Two Case Reports. Annals of Int. Med., 11: 1906-1911, April, 1938.

A review of the literature reveals an indication of a mutual antagonism between the thyroid and islet secretions. No attempt is made to determine whether the antagonism is direct or through the intermediary of some gland such as the pituitary.

Two cases of hyperinsulinism associated with hypothyroidism are reported. In both cases the glucose tolerance test more closely approached the normal response after the basal metabolic rate had been raised to the normal level by feeding desiccated thyroid.

The author concludes that some cases of hyperinsulinism may be improved, if not entirely held in check, by the use of desiccated thyroid, but it is realized that results of such treatment in a large number of cases followed over a long period of time would be necessary be-

fore any trustworthy conclusions could be drawn.

Hanes M. Fowler, Fort Wayne.

ISRAEL, SIDNEY.

Esophageal Obstruction: Case Reports. Texas State Jour. of Med., 33:828-830, April, 1938.

Esophageal obstruction manifests itself with either sudden or gradual onset. Those of sudden onset are generally due to swallowing of a foreign body or an injury, while those of gradual onset are usually due to local inflammation, benign or malignant neoplasms, syphilis, neuropathic functional disturbances, or extrinsic pressure as from mediastinal or glandular involvement.

The most important aids in diagnosis are a complete detailed history, X-ray examination using a thin barium mixture, and esophagoscopy examination under local or general anesthesia as the case demands.

Three cases are reported illustrating obstructions due to stenosis, foreign body, and ulcerated lesions.

Hanes M. Fowler, Fort Wayne.

HUNT, H. B.

Ascorbic Acid in Bronchial Asthma. British Med. Jour., 723: 727, April 2, 1938.

The author reviews the literature relative to the subject and reports the results of treatment in twenty-five cases. The investigation did not show ascorbic acid to be of any value in the treatment of bronchial asthma when given in comparatively large doses either by injection or by mouth.

Hanes M. Fowler, Fort Wayne.

EVANS, N. AND GRAY, P. A.

Laënnec's Cirrhosis. J. A. M. A., 110:1159, April 9, 1938.

Due to the fact that the etiology of Laënnec's cirrhosis is still being debated by clinicians and pathologists, the authors have reviewed 217 cases of it with special reference to its etiology. In examining records of 17,874 autopsies from January 1, 1918, to May 1, 1937, 217 cases were found, an incidence of 1.2 per cent. Arranged chronologically these cases show a definite rise in incidence since the repeal of prohibition. The incidence since repeal is three times that before. One-fourth of the patients were chronic alcoholics, most of whom were males.

In those cases in which cirrhosis was not present, but a history of chronic alcoholism was, the liver frequently showed fatty changes. The authors conclude that chronic alcoholism is definitely a contributing factor in the aforementioned disease.

Francis D. Murphy, Milwaukee.

BASIC OPERATIONS IN COMMERCIAL CANNING PROCEDURES

V. HEAT PROCESSING THE SEALED CONTAINER

● Previously, we have described how raw food material is sealed in the tin container after proper preparatory treatment. After sealing, the next important step in commercial canning is the heat process, or "process" as it is called in the industry.

Essentially, the processing operation involves exposure of the sealed container to hot or boiling water, or to steam under pressure, for the correct period of time. The purpose of the process is to destroy pathogenic or spoilage organisms which may be present on raw food material; the seal on the can then prevents re-infection of the foods by such organisms. Thus, the sealing and processing operations combine to insure a sound, wholesome canned product.

It is not possible here to review all factors which must be considered in the establishment of an adequate heat process for any specific product. Such factors have been briefly discussed in recent publications (1, 2). It must suffice to state that, in general, commercial processing operations are divided into two general types, depending upon the acidity of the food being canned.

The "acid" foods—including the common fruits and certain vegetables or vegetable products whose pH values fall below 4.5—are quite easily heat processed. With such foods it is only necessary to heat the sealed container long enough to permit the attainment of a definite temperature

in the center of the can (usually 200°F. or slightly less). In fact, some acid products may be processed by filling sufficiently hot, sealing and inverting the cans, and cooling without further process.

The "non-acid" foods—such as meat, sea foods, milk and most of the common vegetables—require temperatures above that of boiling water for adequate heat processing. Such foods are processed under steam pressure in a closed "retort", usually at a temperature of 240°F. Years of research have made possible the issuance for the guidance of modern canners of a bulletin listing recommended process schedules for the non-acid products (3).

Regardless of the temperature of processing, equipment is available which permits use of the batch or "still" process, and the "continuous" or "agitating" types of process for sealed cans. Improvements in processing machinery and accessory instruments during the past two decades permit precise, scientific control of commercial processing operations.

Above all, however, the modern canner has a clear understanding of the underlying purpose of the process and a deep appreciation of the necessity for strict supervision of the processing operation. Commercially canned foods, consequently, must be ranked today among the most wholesome foods coming to the American table.

AMERICAN CAN COMPANY

230 Park Avenue, New York, N. Y.

(2) 1937 J Amer. Med. Assn 129, 1946

(3) 1937 Natl. Canners Assn. Bull. 274, 3rd ed.

This is the thirty-eighth in a series of monthly articles, which summarize, for your convenience, the conclusions about canned foods reached by authorities in nutritional research. We want to make this series valuable to you, so we ask your help. Will you tell us on a post card addressed to the American Can Company, New York, N. Y., what phases of canned foods knowledge are of greatest interest to you? Your suggestions will determine the subject matter of future articles.

The Seal of Acceptance denotes that the statements in this advertisement are acceptable to the Council on Foods of the American Medical Association.

YOU GET ALL THREE IN ALL-BRAN

BULK

1 oz. of All-Bran contains as much "bulk" as $7\frac{1}{4}$ oz. of raw cabbage.

VITAMIN B₁

1 oz. of All-Bran contains more Vitamin B₁ than $2\frac{1}{2}$ oz. of whole egg.

IRON

1 oz. of All-Bran contains as much iron as $6\frac{1}{2}$ oz. of fresh spinach.

When you recommend—or use—Kellogg's All-Bran, you are summoning the aid of three important benefits. This natural laxative cereal supplies these great helps in relieving common constipation: "bulk" and vitamin B₁, the intestinal tonic vitamin. As an extra bonus, All-Bran gives a plentiful supply of iron. Made by Kellogg in Battle Creek.

NATURAL LAXATIVE
CEREAL

WARING, J. I.

The Nutritional Factor in Heart Disease in Children. Southern Med. and Surg., 100:119-121, March, 1938.

The author calls attention to heart disease due to nutritional deficiencies as observed in Negro children in Charleston, S. C. The essential findings are those of an enlarged heart with impaired function with a tendency to generalized edema. The cases summarized are not consistent in pointing to a lack of vitamin B₁ as the usual basis of the disease, but suggest a rather more general deficiency of dietary materials. They indicate that a satisfactory response to dietetic treatment may be expected in cases not too far advanced.

Hanes M. Fowler, Fort Wayne.

ATKINSON, A. J. AND IVY, A. C.

Does Removal of a Normal Gall Bladder Affect the Metabolism of Lipids? Jour. of Laboratory and Clinical Med., 23:441, Feb., 1938.

As a result of experiments on dogs, the authors conclude that the rise in fasting plasma lipid levels obtained after cholecystectomy is not specifically due to removal of the gall bladder. It may also be obtained after liver damage, tissue injury, and for a short time after ether or chloroform anesthesia. By studying the blood lipids (total fatty acids, free and total cholesterol) before and after cholecystectomy both under the condition of fasting and during the digestion and absorption of fat, it could not be demonstrated that the gall bladder possessed a function of regulating the metabolism of lipids.

ADEQUATE IRON

for Hypochromic Anemia

Excellent hemoglobin response results in most cases from the daily dose of three Hematinic Plastules Plain. This provides 15 grains of ferrous iron.

Small dosage, easy assimilation and toleration favor the use of Hematinic Plastules for hypochromic anemia, because they produce maximal results, at low cost, without discomfort or inconvenience to the patient.

Hematinic Plastules provide ferrous iron and the vitamin B complex of concentrated yeast, in soluble gelatin capsules. They are issued in two types — in bottles of fifty — Hematinic Plastules Plain and Hematinic Plastules with Liver Concentrate.

ALICATO, J. E. AND SCHLATTENBURG, O. L.

A Case of Intestinal Heterophyidiasis of Man in Hawaii. J. A. M. A., 110:1100, April 2, 1938.

Heterophyid infestation of the intestine in man has been reported from such far eastern countries as China, Japan and Korea, but never before in Hawaii. The case was that of a 26 year old Japanese man who, six weeks before examination had developed a diarrhea which was severe and lasted about three weeks. He had lost about 20 pounds in weight and had a corresponding loss of body strength. When first seen he complained of nervousness and constant discomfort over the colon which was not influenced by the intake of food, defecation or mechanical pressure. His history was essentially negative except for the fact that he liked to eat raw fish, especially "fresh water" mullet and "Chinese eat fish."

Physical examination was essentially negative. Laboratory examination revealed the urine to be negative, the stool negative for amoeba and occult blood. The Weil-Felix test, the Widal test, and the Wassermann and Kline tests were negative. The blood count on one occasion was: hemoglobin 75 per cent, red cells 4,956,000, white cells 9,100, polymorphonuclear leukocytes 47 per cent, basophils 7 per cent, eosinophils 2 per cent, small lymphocytes 44 per cent. On another occasion the white count showed a total of 7,100 of which 37 per cent were polymorphonuclear leukocytes, 4 per cent eosinophils, 12 per cent monocytes and 47 per cent small lymphocytes. Roentgenologically the gastro-intestinal tract was negative except for some irritability of the colon.

Stool examinations were continued and fluke ova were found of the genus *Stellantchasmus*, closely related to, if not identical with, *Stellantchasmus falcatus*. The patient

was placed on oleoresin of aspidium which cleared the condition up rather promptly.

Investigation of local mullet fish in surrounding waters revealed infestation with a heterophyid fluke which was pathogenic for cats. Francis D. Murphy, Milwaukee.

DRUECK, CHARLES J.

Proctitis. Illinois Med. Jour., 73:438-441, May, 1938.

Proctitis, rectitis or inflammation of the rectal mucosa is probably the most frequently encountered of all rectal affections. It is of more common occurrence than generally supposed and is also directly responsible for the production of many disturbances which in turn give rise to symptoms mistaken for distinct diseases. The discussion is confined chiefly to catarrhal proctitis and sigmoiditis, acute and chronic, among the causes of which may be listed the following: irritants such as worms, highly seasoned foods or hard substances in the fecal mass, fish bones and hulls of cereals, constipation and fecal impaction, irritating discharges from above, seasonal changes in food or water, use of strong purgatives, poisonous drugs, irritating suppositories and local extension of inflammation from hemorrhoids or disease of neighboring organs such as the bladder, prostate, vagina or uterus.

The symptoms include sensation of fullness, weight, heat and burning in the rectum, or in severe cases, actual pain that radiates to the sacrum or other pelvic organs or down the thighs. Rectal tenesmus is constant early. The process is essentially an acute inflammation of mucous membrane and resembles that seen in other parts of the body, e. g., the nose. The prognosis is usually good with proper treatment.

A system of treatment is outlined including careful inspection of the rectum, use of castor oil or saline cathartic

ON THE UPSWING TO RICHER BLOOD

with

CHAPPEL

LIV-IRN Tablets

Palatable, economical and quick replenishers of good rich blood, Chappel LIV-IRN Tablets are entirely trustworthy for use in secondary anemias of youngsters. Ingredients: reduced iron, liver extract (sec. anemia fraction) and Vitamins B₁₂, G and D.

Just as dependable in hypochromic anemias are Chappel LIV-IRN Capsules and LIV-IRN Liquid. All LIV-IRN products are chemically, biologically and clinically controlled; lower in cost; prepared from fresh U. S. government inspected livers.

WHEN YOU RECOMMEND GELATINE in the diet, be sure it is KNOX PLAIN SPARKLING GELATINE (U. S. P.)

In order to clear up any confusion that may exist,
we indicate here the difference between a plain
gelatine and a ready-flavored gelatine dessert.

KNOX SPARKLING GELATINE	READY-FLAVORED GELATINE DESSERTS
All 100% gelatine.	Just enough gelatine to make them jell.
Absolutely no sugar.	85% sugar average.
No flavoring. • No coloring. • Just gelatine.	Contain flavoring and coloring matter.
pH about 6.0.	pH highly variable.
Protein 85%.	Protein 10 to 12%.
Knox Gelatine blends well with practically any food.	Almost solely a dessert not readily mixable with other foods.
Practical for a great number of diets which includes—diabetes, acute gastric ulcer, convalescence, anorexia, tubercular, etc.	Usually contraindicated in diabetic, gastric ulcer and other diets.

followed by repeated irrigations of the colon with salt or boric acid solution at 110° F. Following the douching two drams of 25% solution of fluid extract of hydrastis is injected into the rectum to be retained. If ulcers are found on the rectal wall they are treated locally by painting with pure ichthylol or 5% silver nitrate solution.

The diet should be carefully arranged so as to be non-irritating and of such variety as will insure soft or semi-solid evacuations. As the inflammation subsides, constipation is apt to occur and a full glass of flaxseed tea at night will be found to act as a mild laxative and at the same time is soothing to the intestine. A recipe for flaxseed tea is given.

The patient should be kept in bed until all pus and blood have disappeared from the stools.

Hanes M. Fowler, Fort Wayne.

JOHNS, HENRY J.

The Outlook for Diabetic Children. Southern Med. and Surg., 100:103-110, March, 1938.

The author estimates that there are some 1000 new diabetic children each year who now live as compared to approximately 1000 diabetic children who died yearly in the pre-insulin era. Heredity is an important factor in the etiology of diabetes in that it is believed that the condition of the island apparatus is determined thereby. Infection is also an important factor, especially in precipitating active cases among so-called border-line cases.

As diabetic children reach adulthood and marry, attention must be directed to the hereditary aspects of the condition. A diabetic child is not necessarily handicapped physically or mentally provided his nutrition is kept up satisfactorily, which entails the proper use of diet and insulin.

One of the disquieting things in the management of diabetic children is the progressiveness of arteriosclerosis which seems to be appearing at an early age.

With the 15 years of the insulin era a complete transformation has taken place in the outlook for the diabetic child. With the facilities at hand for properly controlling the condition, diabetic children can now look forward to doing practically all the things that non-diabetics can do.

Hanes M. Fowler, Fort Wayne.

EDCOCKE, BANNER R.

Colonic and Rectal Cancer. Northwest Medicine, 57:81-83, March, 1938.

The author cites figures to substantiate his conclusion that the incidence of colonic and rectal cancer has increased during the past 15 years or so. He also stresses the importance of early recognition of the condition.

The incidence of rectal and colonic cancers is about equal, with about half as many located in the right side as in the left side of the colon. Gastric disorder, early tumefaction, and early cachexia are prominent symptoms of right-sided malignancy. Obstruction, partial or complete, and borborygmus are found more often in left-sided cancer, but seldom in rectal cancer. Bright blood in the stool must always be regarded as possible cancer. Sigmoidoscopy and colon roentgenogram should be demanded at once. These procedures should be repeated, if the bleeding persists, until its site has been determined.

The public must be informed of these early symptoms even at the risk of increasing cancerphobia and neurosis. The profession must be more alert in the early identification of colonic and rectal cancer.

Hanes M. Fowler, Fort Wayne.

For HYPERACIDITY and the medical management of PEPTIC ULCER

COLLOIDAL
ALUMINUM
HYDROXIDE
(TRUESDALE)

THE etiologic role of excess gastric acidity in the development of peptic ulcer renders its control imperative in cases where ulceration is feared or has already progressed.

Colloidal Aluminum Hydroxide (Truesdale) provides a safe, efficient agent . . . as a help in the prevention of ulceration, or as a positive stimulus to the healing process. Prepared by special process, it is rigidly standardized to contain 4% to 5% of alumi-

num hydroxide with approximately 0.5% sodium chloride. By direct titration, using Töpfer's reagent, it can adsorb and neutralize more than 10 times its volume of N/10 hydrochloric acid in 10 minutes; and more than 12 times its volume in 30 minutes.

Thus it prevents unbuffered gastric juice from coming into contact with the ulcer itself, and by its unusual astringent and demulcent properties, helps to control hematemesis, and provide immediate mechanical protection against irritation. Important for the relief of pain is its efficacy in reducing hyperperistalsis and pylorospasm.

No deleterious effects follow its ingestion. It does not disturb the acid-base balance, nor cause evolution of gas, nor stimulate a secondary acid rise.

By oral administration, ambulatory cases may be successfully relieved.

By continuous drip administration, severe cases yield the largest percentage of cures in the shortest period of time.

Send now for samples
and complete literature

Persistent ^{B₁}Anorexia

A RECOGNIZED INDICATION FOR VITAMIN B₁

ANOREXIA is often closely connected with deficiency of vitamin B₁ which manifests itself also by reduced secretory and motor activity of the gastrointestinal tract. The patients who can be benefited by the administration of vitamin B₁ include those with a failing appetite and malnutrition and those in whom the appetite and nutrition have been impaired by an acute or chronic

exhausting illness, with an accompanying hypovitaminosis.

The importance of providing the growing child with an adequate supply of vitamin B₁ is also generally recognized.

The presence of polyneuritis in beriberi is striking evidence of the detrimental influence of marked vitamin B₁ deficiency upon the peripheral and central nervous system. Therefore, it is likely that in neuritis of obscure origin the causative factor may be B₁ avitaminosis. This is borne out by the encouraging results which have been reported in polyneuritis and various other types of neuritis (facial, brachial, occipital, femoral). In the treatment of alcoholic neuritis also, vitamin B₁ appears to be of definite value.

HOW SUPPLIED: Tablets of 0.1 mg., 0.5 mg., and 1 mg., bottles of 50; tablets of 5 mg., bottles of 25 and 500. Ampules of 1 mg. (1 cc.), boxes of 10 and 100, ampules of 10 mg. (1 cc.), boxes of 5 and 25. Vials of 100 mg. (10 cc.)

Studies in Absorption of Undigested Protein in Human Beings: VII. Absorption of Protein Introduced by Tube into the Duodenum*

By

IRVING GRAY, M.D.

and

MATTHEW WALZER, M.D.

BROOKLYN, NEW YORK

IN a previous study (1) the writers found that the rapidity of absorption of unaltered protein following its oral administration was directly influenced by the degree of gastric acidity. In the presence of hyperacidity, the absorption of unaltered protein was definitely retarded. In hypoacidity it was accelerated. In order to obtain further information on the factors influencing absorption from the upper digestive tract, it was decided to administer the test meal by duodenal intubation directly into the intestines. In this manner, interference with the emptying of the stomach could be excluded as a mechanical factor influencing the rapidity of absorption, and the importance of the acid role could be more clearly evaluated.

Peanut was the protein selected for this investigation. This choice was determined solely by the circumstance that there was available at the time a serum which was particularly suitable for the study of this antigen. This serum was the same one which had been employed in the previous study on absorption of proteins following its oral administration (1).

The method for determining the absorption rate is an immunologic one which has been described in great detail in previous communications (3). It may be briefly summarized as follows:

Peanut is excluded from the subject's diet for twenty-four hours preceding the test. One-twentieth of a cubic centimeter of a 1 to 10 dilution of the sensitizing serum is introduced intracutaneously on the forearm of the subject. (This serum had been obtained from a patient who manifested a very marked reaction to an intracutaneous test with peanut extract in a very high dilution and who was extremely sensitive clinically to this food). On the morning after the passive local cutaneous sensitization, the subject is given the peanut test meal on an empty stomach. The meal consists of a "milk" made by dissolving 10 grams of raw ground peanuts in 30 cc. of water, to which is added 1 gram of sugar and .05 cc. of oil of cloves. The entrance of the unaltered peanut protein into the circulation is marked by the onset of a reaction at the sensitized cutaneous site. Pruritis is usually the first symptom noted. Erythema and wheal formation follow rapidly. The absorption time is the interval which elapses between the consumption of the test meal and the appearance of the first objective sign at the sensitized site; namely, erythema or wheal.

For the administration of the test meal in the present study the duodenal tube was passed on a fast-

ing stomach and the position of the bucket was localized with the aid of the fluoroscope. When it was visualized in the duodenum and bile was obtained on aspiration, the peanut meal was injected through the tube.

Individuals with frank atopic illnesses, such as hay fever and asthma were not used as subjects for study.

for it has been demonstrated (2) that such persons do not accept local cutaneous sensitization with the same degree and regularity as do normals.

The 46 subjects studied were adult patients of both sexes who, in most instances, suffered from some functional or organic disease of the gastro-intestinal tract. The diagnoses in these cases were arrived at after the completion of thorough laboratory, X-ray and clinical investigations.

The degree of gastric acidity was determined either by fractional gastric analysis or by a Boas test meal. In most instances, where an abnormal gastric acidity curve was obtained, the analyses were repeated in order to check the findings.

As in the previous study, the cases were roughly classified according to the amount of gastric acidity which they presented (1). Individuals who had a variation in free hydrochloric acid between 20 and 30 degrees and a total acidity between 30 and 40 degrees

*From the Department of Applied Immunology of the Jewish Hospital of Brooklyn, N. Y.
Read at the Spring Meeting of the Society for the Study of Asthma and Allied Conditions, Atlantic City, New Jersey, May 2, 1937.
Submitted November 10, 1937.

were considered normal. When the free hydrochloric acid was constant at 40 degrees or over and the total acidity constant over 60 degrees, a state of hyperacidity was considered present. In the hypoacidity group were placed those subjects in whom free hydrochloric acid was constant at less than 10 degrees and in whom total acidity was constant under 20 degrees.

77	29	M	Duodenal Ulcer	19
83	31	M	Duodenal Ulcer	20
Average Absorption Time in Minutes				23.9

Patients in whom no free hydrochloric acid was found were not encountered in the present study.

According to the above standards, 12 patients fell into the normal acidity group. The findings on these cases are summarized in Table I. The absorption times in this group varied from 12 to 23 minutes. The average for the entire group was 16.4 minutes.

In Table II are listed the results obtained in the 10 cases with hyperacidity. The absorption times in this group varied from 14 to 31 minutes. The average rate of absorption was 23.9 minutes.

In Table III are listed the ten cases with gastric hypoacidity. Among these the absorption time varied from 11 to 24 minutes. The average was 16 minutes.

Comparing the results obtained in these groups, it will be noted that, although there is little difference between the average absorption times of the normal and hypoacidity cases (16.4 and 16 minutes respectively) there is a definite delay in absorption in the hyperacidity group, the rate in the latter group being 23.9 minutes, an increase of 45.7% over the normal. This is virtually the same result which was obtained in the previous study when the peanut protein was given orally. Under those conditions, the normal average was 18.7 minutes and the hyperacidity average 27.5 minutes, an increase of 47% over the normal.

In the present study as in the previous one, the reading of the hypoacidity group differed less from the normal than did that of the hyperacidity group. When the meal was given directly into the duodenum the average reaction time in the cases with hypoacidity was 16 minutes, an acceleration of only 2.4% over the reading in the normal acidity group (16.4 minutes). In the oral study, the hypoacidity average was 15.9 minutes, an acceleration of 15% over the normal time (18.7 minutes). These results do not indicate an un-

equal influence on absorption by different degrees of acidity. The explanation for this variation in results probably lies in the arbitrary standards which were adopted for the classification of cases. The limits of acidity readings for the hypoacidity groups (all below 10° free and 20° total acid) are much narrower than those of the hyperacidity group (all above 40° free and 60° total acid).

The average absorption time for the entire series of 32 cases studied by duodenal feeding of the protein was 18.7 minutes. This was several minutes shorter than the average obtained in the previous study in which the peanut meal was given orally. A direct comparison of the results in the two series was not permissible, however, as the two studies were not made on the same subjects with the same batch of sensitizing peanut serum.

In order to obtain more reliable data on the comparative rates of absorption following oral and duodenal feedings of the antigen, a series of 14 subjects were tested by both methods, using the same serum. Only a few days were allowed to elapse between the oral and duodenal testings of each patient.

The results obtained in each subject by the oral and by the duodenal feeding of the antigen are listed in Table IV. In this group of 14 cases, the average absorption time following the duodenal administration of the protein was 18.6 minutes. This was more rapid by 5.7 minutes than the average oral time (24.3 minutes) in the same cases. In every subject but one, the duodenal administration of the antigen reduced the oral absorption time by a period varying from 1 to 17 minutes.

The influence of gastric acidity upon the rate of absorption of unaltered protein was again demonstrated in this comparative study (see Table V). With the

TABLE III

Average Absorption Time in Minutes				16

duodenal as well as with the oral administration of the test meal, absorption was retarded in cases with hyperacidity and accelerated in individuals with hypoacidity, as compared to the normal acidity rate for each method of feeding.

It is also of interest to note that the differences between the oral and duodenal absorption rates mounted

as the degree of gastric acidity increased (see Table V). Thus, the absorption rate was less with duodenal than with oral feeding by 1.8 minutes in the hypoacidity group, by 6.2 minutes in the normal acidity cases, and by 9.3 minutes in the hyperacidity group.

Absorption studies upon unusual cases offered an opportunity to determine the influence of mechanical

delayed in both instances. They were 23 and 26 minutes respectively, whereas the average absorption rate for the normal acidity group of the same series (see study VI) (1) was 18.7 minutes and in the hyperacidity group 27.5 minutes. These findings clearly demonstrated that the delay in absorption in patients with gastric hyperacidity could not be attributed to

TABLE IV

factors upon the rapidity of absorption of unaltered protein from the upper digestive tract.

Two patients, upon whom posterior gastro-enterostomies had been performed several years previously for the relief of chronic duodenal ulcers, were submitted to the absorption tests. Repeated gastric extractions on these individuals always revealed the presence of hyperacidity. Fluoroscopic and X-ray examinations disclosed in each case a normally functioning gastro-enterostomy. Despite the fact that the emptying time of the stomach in these patients was more rapid than normal, the absorption rates when the peanut test meals were given orally were found to be

TABLE V

Relation of the degree of gastric acidity to absorption times following oral and duodenal administration of peanut protein in fourteen cases

Degree of Gastric Acidity	Number of Cases	Average Absorption Time in Minutes	
		Oral	Duodenal
Hypoacidity	4	17.5	15.7
Normal	6	24.5	18.3
Hyperacidity	4	31	21.7

any tardiness on the part of the stomach in emptying itself.

Under certain circumstances, however, organic disease, which mechanically interferes with the normal function of the pylorus may be responsible for delaying the absorption of ingested protein. This was well illustrated in three patients with gastric carcinomas which, in each instance, produced incomplete pyloric obstruction. Gastric extractions revealed little or no free hydrochloric acid in these cases. Following the oral administration of the peanut meals, the absorption rates were 46, 51 and 62 minutes respectively. These were far in excess of the averages for the other hypoacidity and anacidity cases in the same series, which were 15.9 and 11.7 minutes respectively (see Study VI) (1). These findings demonstrate that the mechanical interference with the passage of food from the stomach into the duodenum can and does delay the absorption of unaltered antigen into the circulation. They also offer suggestive evidence that there is no absorption of undigested protein from the stomach itself in pathologic cases of this type.

SUMMARY

1. Following the intra-duodenal administration of a peanut test meal, the rate of absorption of unaltered peanut protein is more rapid by several minutes than the rate following its oral consumption.

2. In patients with gastric hyperacidity the absorption rate from the duodenum is not as rapid as in those with normal gastric acidity.

3. In patients with gastric hypoacidity the absorption rate from the duodenum is more rapid than in patients with normal gastric acidity.

Bile Salt Therapy in Gall Bladder Disease*

By

HENRY DOUBILET, M.D., HARRY YARNES, M.D.

and

ASHER WINKELSTEIN, M.D.

NEW YORK, NEW YORK

THE symptoms of chronic gall bladder disease may be divided into three distinct groups: (1) pain, commonly called biliary colic, (2) indigestion, or dyspepsia, under which may be included pyrosis, belching, gaseous distention and flatulence after meals, and (3) constipation. The attacks of pain are not colicky in nature in the true sense of the word, since the pain may last continuously without intermittent periods of freedom, anywhere from ten minutes to several days. The pain commonly starts in the epigastrium or right upper quadrant and tends to spread to right and left in a girdle fashion, and upwards to the right shoulder blade. It is usually described as either compressing or distending in character. Very often there is present in addition a penetrating pain, which passes through directly from the epigastrium to the back. Depending on the individual, the pain may be felt in all these regions, or in one place only.

Following cholecystectomy it is estimated that the attacks of pain recur in approximately 20% of cases (1, 2), usually somewhat milder in character but occasionally as severely. This recurrence is blamed on residual or newly formed common duct stone or intra-hepatic stones, recurrent pancreatitis, duodenal adhesions, hepatitis, or spasm of the sphincter of Oddi. A stone in the common bile duct is occasionally found at a subsequent operation. Rarely there is definite evidence of pancreatitis. Very often no explanation can be offered except the possibility of recurrent spasm of the sphincter of Oddi. This is known to exist in the human and this idea is supported by observations that attacks tend to occur during states which may be accompanied by gastro-intestinal spasm, i.e., periods of emotional upset, during the menopause in women, and following periods of severe constipation. In addition it has been noted that occasionally the attacks tend to disappear after the first year following cholecystectomy. This may be due to the fact that, as Judd and Mann have shown experimentally, the sphincter of Oddi tends to lose its tone and become incompetent after cholecystectomy (3). The loss of tone is however only functional since an appropriate stimulus, such as hydrochloric acid, may cause recurrence of the spasm (4). The reappearance of attacks of pain after a free

interval of five or six years following cholecystectomy may thus be explained.

It is difficult to account for the indigestion and constipation which so often accompanies gall bladder disease. It may be due in part to reflex spasm of the gastro-intestinal tract as a result of biliary pain. However since this dyspepsia tends to remain as a residual symptom in a large proportion of patients in whom pain has been relieved by cholecystectomy (5), other factors must be considered. One must always consider the possibility that gall bladder disease may be secondary to some primary dysfunction of the gastro-intestinal tract, made manifest by the various symptoms associated with dyspepsia. However there can be no doubt that a considerable number of patients with gall bladder disease are relieved of their dyspepsia after cholecystectomy. There may be, however, an other possible explanation for many of the gastro-intestinal symptoms associated with gall bladder disease. It is known that bile salts are of great importance in the process of digestion, especially of fat digestion. A point that has never been stressed sufficiently is the effect on the storage of bile salts if the gall bladder has been rendered functionally incompetent by disease or stones, or has been removed by operation. Normally the gall bladder contains about 75 cc. of bile, having a bile salt concentration of about 8%. Following the ingestion of food, the gall bladder pours into the intestine about six grams of bile salts in concentrated solution. If the gall bladder cannot empty or is absent there is present only a continuous flow of thin bile from the liver, containing a relatively dilute solution of bile salts. In addition, in the absence of the gall bladder as a storehouse, the body can keep in the entero-hepatic circulation only a small amount of bile salts, since there is probably no other place in the tissues where such a toxic substance could be stored in any quantity.

It is difficult to prove directly that there is a quantitative loss in the amount of bile salts in circulation in the body. Duodenal drainage removes only a portion of the biliary output. Recovery of bile by means of a fistula breaks up the entero-hepatic circulation and gives abnormal results. However, in a series of fistula bilcs analysed for bile acids, definite evidence was found indicating that many cases of chronic cholecys-

*From the Gastro-Intestinal Clinic of the Outpatient Department, The Mount Sinai Hospital, New York.
Submitted December 30, 1937.

titis have a bile acid concentration much lower than normal (6).

A more direct approach that would indicate that the dyspeptic symptoms and constipation in gall bladder disease might be due to partial lack of bile salts, would be to feed bile salts in adequate amount. The gall bladder contains about 75 cc. of bile (7) with a bile salt content of about 8% (8), and empties ordinarily about three times daily. A simple calculation indicates that during the course of daily digestion probably about 15 to 18 grams (225-270 grains) are poured into the intestinal tract. It would seem evident then that the dosage of bile salts formerly recommended and used (9, 10), would as a rule be inadequate, and yield rather unsatisfactory results. A series of cases in which large and more adequate amounts of bile salts were used was recently reported by Rosenak and Kohlstaedt (11).

In this presentation the results of treatment in 38 cases of various types of gall bladder disease are reported. The therapy was based on two principles: (1) a suitable diet and (2) administration of bile salts. It

TABLE I

Low carbohydrate, low fat, gall bladder diet

GENERAL RULES:

1. Eat lean meat, vegetables and fruit.
2. Drink plenty of water.
3. Eat three meals a day.
4. Do not eat between meals.

AVOID:

Fats—egg yolks, cream, butter, fat meats and fish, cream soups, fried foods, mayonnaise, oil, ice cream.

Carbohydrates—sugar, pastry, candy, potatoes, excess bread or crackers.

Meats—pork, duck, goose, any fat meat, gravy of all kinds.

Fish—salmon, sardines, herring, tuna fish, mackerel.

Vegetables—potatoes, corn, lima beans, fresh peas, kidney and navy beans.

USE:

Meats—(roast, grilled, boiled or baked). Lean roast beef, steaks, veal chop, veal cutlet, roast veal, lamb chops, roast lamb, sweetbreads, chicken.

Fish—Haddock, perch, smelts, cod, pike, halibut, lobster.

Vegetables—Asparagus, celery, cucumber, egg plant, lettuce, sour grass, spinach, squash, string beans, tomato, beets, carrots, onions, canned peas, turnips.

Desserts:

Fruits—Blackberries, canteloup, honeydew, grapefruit, peach, pineapple, strawberries, watermelon, apples, apricots, blueberries, pears, cherries, raspberries.

Pot cheese.

Jello, water ices.

DIET:

Break fast:

- 1 serving fresh fruit.
- 1 slice bread
- 1 cup coffee or tea with skimmed milk and no sugar.

Lunch and dinner:

- 1 serving soup (clear meat soup without fat, vegetable soup or tomato soup without cream or butter).
- 1 large serving lean meat or fish.
- 2 serving vegetables.
- 1 serving dessert, if desired.
- coffee or tea.

is well known that many people suffering from gall bladder disease have an intolerance for fats even after the gall bladder has been removed. In addition, since the gall bladder contracts actively following the ingestion of fats it would seem desirable to prevent such active contraction in a functioning gall bladder containing stones which could be forced into the cystic duct. Olive oil and oleic acid have been used in gall bladder therapy for many years on the theory that the frequent emptying of the viscous would prevent stasis and gall stone formation. It is notorious, however, that most patients with gall bladder disease cannot tolerate fatty meals. They are much more comfortable on a low fat diet; in addition it has been shown that the gall bladder will gradually empty even on a pure carbohydrate diet (12).

Whipple has shown experimentally that proteins stimulate the formation of bile salts, while carbohydrates tend to diminish their formation and also produce a thick viscid bile. Since most gall bladder patients are overweight, all these factors were considered in the elaboration of a low fat, low carbohydrate, high protein diet (Table I). An effort was made to produce an habitual gastro-intestinal rhythm, by requiring the patients to take their meals at regular hours and not to eat between meals.

On the principle that bile salts might be lacking in patients with gall bladder disease suffering from dyspeptic symptoms, from 15-60 grains of bile salts were administered daily. The therapeutic index taken to determine an adequate dosage was the control of constipation. All cathartics being stopped, the amount administered was gradually raised from 5 grains with each meal until bowel movements occurred at least once and not more than twice daily. As a rule about two weeks was necessary to stabilize the dosage. Once standardized, the amount each patient took daily could be maintained for many months. The average dose was from one to three 5 grain capsules at each meal.

In order to introduce the added bile salts at the optimum time to aid digestion, the capsules were administered in the midst of each meal. This allowed the bile salts to be mixed thoroughly with the food and prevented any tendency to gastric irritation. It was found that the administration of large amounts of plain bile salts often caused such gastric irritation. To overcome this an iron salt of ox bile acids in purified form was used.* This salt is insoluble in acid medium and accordingly does not dissolve in the stomach. As a result enteric coated capsules are not required for its administration. Once it is mixed with the alkaline duodenal contents it dissolves readily at the optimum point for emulsification and absorption of food.

Treatment was carried out on three groups of patients:

- (1) Cases with post-cholecystectomy symptoms.
- (2) Patients with functioning gall bladders containing stones (as determined by roentgen-ray visualization after dye administration).
- (3) Patients in whom the gall bladder could not be visualized.

Results:

Group 1—Patients with the post-cholecystectomy syndrome.

*This iron ox bile salt was at first made in Germany by Dr. G. H. B. but has since been purified by courtesy of the Lilly Co.

The results on 13 cases are tabulated (Table II). All patients except one (F.M.), were relieved of their dyspeptic symptoms and constipation. Six were relieved of their pain, and four showed marked diminution of their pain. One patient (A.R.) had persistent left upper quadrant pain without improvement. This was possibly due to pancreatitis. Another patient (R.S.) was found to be suffering from spondylitis and radiculitis, the pain of which was not relieved by our therapy. The third unrelieved case was a patient who apparently showed no improvement on 90 grains of bile salts daily. The persistence of the constipation led to the suspicion that she was not taking the medication. However this patient must be recorded as a complete failure of the treatment. It is noteworthy that treatment with mineral oil or such cathartics as Carlsbad salts, rhubarb and soda, or magnesium sulphate relieved the constipation, but neither the dyspeptic symptoms following meals nor the attacks of pain. In one patient (J.E.) the administration of atropin seemed to help in the control of attacks of pain.

Group 2—Cases with functioning gall bladders containing stones.

A group of 14 patients in whom the Graham-Cole radiographic examination revealed the presence of stones in a gall bladder capable of filling and emptying, (i.e., normal visualization and emptying after a fat meal) were put on a therapy of a low fat diet and bile salt administration (Table III). In all these cases

dyspepsia and constipation were relieved. In eight patients attacks of were also relieved. Four patients showed marked improvement in that the frequency and severity of pain attacks were reduced. Two of these patients, after 4 months therapy, developed an acute attack—one case (F.K.) after a fatty meal, and the other (F.A.) following a duodenal drainage in which olive oil was injected to obtain "B" bile.

One patient (C.P.) had marked gastric hyperacidity. Diet and bile salt therapy did not control the attacks of pain, which were apparently associated with the hyperacidity. It has been shown previously that application of acid to the papilla of Vater causes spasm of the common duct sphincter. This reflex spasm can be abolished by atropin (4). It seemed possible that in this case the frequent attacks of pain were due to recurrent spasm of the sphincter of Oddi. Accordingly alkalies and atropin were administered with marked relief of pain. Two other cases with hyperacidity (F.K. and M.R.) were well except for an occasional attack of pyrosis. In another patient (F.S.) in whom therapy failed, operation revealed a small stone lying in one of the valves of Heister in the cystic duct. The slightest flow of bile in either direction through the duct would tend to cause obstruction of the ball-valve type. In such cases only surgical intervention could lead to relief. We have since encountered two similar cases in whom failure of a short course of therapy led to the suspicion of the presence of a cystic duct stone. In both cases a stone was found in one of the valves of Heister at operation.

TABLE II
Cases with post-cholecystectomy symptoms

Name	Age	Sex	Symptoms			Bile Salt Therapy		Result of Therapy			Remarks
			Pain	Dyspepsia	Constipation	Daily Dosage Grains	Duration Therapy Months	Pain	Dyspepsia	Constipation	
B. E.	32	F	+	+	+	45	8	A	A	A	Attack of epigastric pain while on control period of mineral oil only.
J. E.		F	+	+	+	60	8	B	A	A	Nervous patient with coronary artery disease; atropin was helpful in therapy.
E. G.	56	F	+	+	+	15	18	A	B	A	Control period on rhubarb and soda only resulted in attacks of pain.
F. M.	34	F	+	+	+	90	2	C	C	C	Neither bile salts nor low fat diet had any effect on symptoms.
A. R.	43	F	+	+	+	30	6	C	A	A	Left upper quadrant pain prior to and after operation; pancreatitis (?).
S. S.	39	F	+	+	+	30	21	A	A	A	Control period on Carlsbad salts resulted in recurrence of symptoms.
G. S.	33	F	+	+	+	15	12	B	A	A	Well for 10 months; attacks of pain and diarrhea then recurred.
R. S.	54	F	+	+	+	90	4	C	A	A	Pain was found to be due spondylitis and radiculitis.
R. N.	53	F	0	+	+	30	4	A	A	A	
R. J.	45	F	+	+	+	30	1	B	A	A	Pain was in left upper quadrant and recurred after one month's treatment.
T. G.	38	F	+	+	+	30	3	B	A	A	Achlorhydria present; functioning gall bladder without stones removed at operation.
J. S.	47	F	+	+	+	15	6	A	A	A	Has continuous dull ache in R.U.Q. due to adhesions.
F. L.	59	F	+	+	+	20	3	A	A	A	Control period on magnesium sulphate resulted in recurrence of symptoms.

Notes:
A—Relieved B—Improved C—Unchanged

The impression was gained that in patients in whom therapy was stopped either deliberately or due to a temporary lack of a supply of bile salts, the symptoms both of pain and dyspepsia tended to recur. Five patients in whom constipation was overcome by administration of magnesium sulphate, Carlsbad salts, or rhubarb and soda, during a control period, were however, not relieved of dyspepsia or pain.

Group 3—Cases with non-visualized gall bladders.

A series of 11 patients in whom the gall bladder did not visualize after dye administration, were also treated by diet and bile salt therapy (Table IV). The presence or absence of stones could not be determined. Dyspepsia and constipation were overcome in all cases. Eight patients were rendered free of pain, although in one case (R.M.) bile salt therapy had to be stopped when an attack of mucous colitis recurred. Two patients showed marked improvement in that the frequency and severity of attacks of pain were reduced. One of these patients (K.H.) had marked gastric hyperacidity, while in another patient (F.B.) repeated dietary indiscretions resulted in many attacks of pain.

DISCUSSION

Our experience indicates that the majority of patients who suffer from pain and dyspepsia after cholecystectomy can be relieved by a fat free diet and by an adequate intake of bile salts. Certain exceptions, however, must be carefully noted. If a choledochal stone is present, the increased flow of bile following bile salt administration results in accentuation of symptoms or even the appearance of jaundice. Such a condition was noted in two patients. In one of these, previously reported (13), bile salt therapy increased the frequency of attacks. At operation, a small stone was found in the common bile duct, although no jaundice was ever present. In the other patient bile salt therapy resulted in the appearance of jaundice. At operation two choledochal stones were found.

Any condition, such as partial stricture, malignancy, or chronic pancreatitis which would diminish the diameter of the common bile duct, could cause increase in symptoms on bile salt therapy. In one case jaundice developed soon after administration of bile salts. At operation malignancy of the common bile duct was

found, resulting in incomplete stricture. The increased flow of bile resulted in obstruction and jaundice. It follows therefore that bile salt administration may prove useful as a test for the presence of partial organic obstruction.

The presence of gastric hyperacidity renders treatment very difficult. In such cases the frequent attacks of pain seem to be due to the recurrent spasm of the sphincter of Oddi. The addition of atropin and alkalies to the therapy is of great assistance. The neurotic patient is also difficult to treat, since any emotional upset brings on an attack of pain. This is apparently due to a spastic condition of the gastro-intestinal tract which involves, among other sphincters, the common duct sphincter as well.

It is difficult to explain the disappearance or reduction in the number of attacks of pain when bile salts are administered. It would seem that the increased flow of bile from the liver, the disappearance of the difficulty in digestion and the improvement in intestinal peristaltic action all tend to eliminate the tendency to gastro-intestinal spasm. In support of this it has often been noted that the relief of constipation only by the ordinary saline cathartics is occasionally of some assistance in the improvement of painful symptoms.

The cases in whom the gall bladder was still present, are presented not primarily to recommend this form of therapy as the preferred treatment for gall bladder disease, but to point out that these patients may be treated satisfactorily medically. This therapy is especially important in old and debilitated people, in cases with associated cardiac disease, or other con-

ditions where operation is dangerous, and also in people who refuse operation.

The removal of a functioning gall bladder containing a few stones should be deprecated on general physiologic principles, since its important function as a storehouse for bile salts would be lost. Medical therapy should be attempted before operation is advised. However there is often great difficulty in keeping such patients on a fat free diet to prevent active contraction of the gall bladder. Certainly in many cases, especially where a small stone is present in the cystic duct, no diet can be rigid enough to prevent attacks of pain due to recurrent impaction of a stone.

In addition to these difficulties, the problem is raised whether it is not preferable to remove a gall bladder containing stones as soon as the diagnosis is made, rather than to wait for more serious complications to ensue later in life. The question cannot be discussed here. The point we should like to stress is that the treatment of patients suffering from gall bladder disease cannot be condensed to a few rule of thumb directions. Our experience, however, indicates that if one keeps constantly in mind the known physiologic principles of the biliary and gastro-intestinal tracts, one can achieve considerable success in the therapy of gall bladder disease.

SUMMARY

(1) 3 groups of patients with gall bladder disease are described.

(2) The use of a low fat diet and large amounts of bile salts is advocated in the treatment of these cases.

(3) In the group (13 cases) with the type of post-cholecystectomy syndrome not due to organic obstruc-

tion, relief was obtained in most of the cases with this form of therapy.

(4) In two other groups, i.e., those with stones and normally functioning gall bladders (14 cases) and those with chronic gall bladder disease in whom the gall bladder failed to visualize (11 cases) considerable

relief from symptoms was also obtained.

(5) In the cases in whom gastric hyperacidity was present atropin and alkalies were helpful adjuvants in the therapy.

(6) In view of these results, the use of this mode of therapy in a larger group of cases seems advisable.

The Symptomatology of Gastritis

By

JAMES B. CAREY, M.D.*
MINNEAPOLIS, MINNESOTA

THE interest of most workers in the field of gastric pathology has been directed toward classification and possible etiological relationship of various conditions, one to another. The result has been a considerable literature concerned with histologic study of postmortem or resected material, and objective description of appearance at operation, of necropsy material, radiography and gastroscopy. There are certain wide discrepancies apparent—largely due to differences of interpretation of actually identical conditions and the drawing of unwarranted conclusions from limited methods or material. There is as yet, for instance, no common definitive basis upon which to explain gastroscopic pictures, roentgenographic "relief technic" films, formalized autopsy material, surgically resected tissue or the various phenomena of gastric secretions. Only isolated and casual attempts have been made to translate gastroscopic discoveries in terms of clinical manifestations or symptomatology, particularly with reference to gastritis.

Schindler (1) has recently stated that "all authors who have made gastroscopic examinations in many cases of chronic gastritis have agreed that the symptomatology is so vague that neither diagnosis nor classification on a symptomatologic basis is possible, 'that the most any one can ascertain of the patient's symptoms are anorexia, pressure in epigastrium, disinclination to work, and occasionally severe pain if severe erosions or hemorrhage of mucosa be present, and concludes that 'at this time' diagnosis of chronic gastritis on basis of symptoms is impossible." It was Schindler who in 1922 (2) on the basis of gastroscopic studies pointed out the frequency of chronic gastritis; herein was set forth the different forms of gastritis and in a subsequent review (3) of his material an attempt was made to evaluate symptoms in relation to these various forms.

Gutzeit (4) also says that the clinical diagnosis of gastritis is difficult because gastritis may take on nearly all the symptoms of the various abdominal diseases. He could not find any correlation with acid values. Many times he found various nervous and traumatic factors in the history (he probably did not segregate the psychoneuroses), and altogether he seems inclined to think, because of the confusion of symptoms, that gastritis may be a part of a general gastro-enterocolitis. In spite of these conclusions, from cases cited by him (5) the usual history seems to be that of pain or some kind of distress immediately after meals with loss of appetite—often weight loss—and irregularity of bowels (constipation or diarrhea) occurring at intervals over a long period of years. Often the pain occurred late after meals as in ulcer, but was seldom as well localized. Occasional belching with bitter or sour eructation occurred.

Moutier (6) precedes his discussion of gastritis by recognizing "the difficulty of establishing a relationship between the microscopic appearance, the histological lesions, the secretory values, and the clinical pictures." He attempts to establish pictures of primary gastritis by classification according to probable etiology. For instance, in acute gastritis he recognizes two forms: "Toxic-infectious" and "Chemical." Of the clinical forms of chronic gastritis, he lists: "Toxic" (lead and alcohol) and dyspeptic, where the symptoms occur either early or late after meals, with eructation, bloating, pyrosis, somnolence, fatigue and headache. The pain may be epigastric or umbilical in location, or diffuse. When these dyspeptic symptoms are produced by superficial and atrophic forms of gastritis the distress is present with or immediately after meals, the distress in the hypertrophic form usually is late and may be more severe and cramplike. The ulcerative forms are likely to have continuous pain, but night pain is rare with any form. He concludes, as he began, by saying that up to the present it is impossible to

*From the Department of Medicine, Medical School, University of Minnesota, and the Division of Medicine, The Nicollet Clinic.

define syndromes which will include clinical, laboratory, pathological and gastroscopic data.

Benedict (7) in a study of forty cases of gastritis, lists the symptoms epigastric pain or distress, nausea, vomiting, eructation, heart-burn, gas, anorexia, fullness, hematemesis and melena, of which epigastric pain and distress are the most constant complaints, with gas, nausea and vomiting frequent, and hematemesis and melena not uncommon. He emphasizes evidences of hemorrhage either gross or occult as strongly indicative of gastritis when X-ray reports have been negative. About one-half of his gastritis cases have shown some evidences, clinically, of hemorrhage.

In the cases which Faber (8) describes of rather severe erosive gastritis, the history was that commonly considered characteristic of peptic ulcer, namely, late post cibum pain, night pain, food relief, occult hemorrhage, periodicity and chronicity. He found in these severe gastritis cases further "ulcer symptoms," i.e., hyperacidity, hypersecretion, nausea, vomiting, various degrees of retention and pylorospasm. The similarity between symptoms of gastritis and ulcer is explicable on the assumption that either locally or generally inflamed mucous membrane responds to increased peristalsis (irritable hypermotility, spasm or hunger contractions) with sensation of pain.

Katsch (9) has classified the symptoms of gastritis into six groups:

1. Sensitive stomach—"acidism," epigastric burning, heart burn, eructation.
2. Pyloric syndrome—includes postcibum pain, nausea and vomiting.
3. Dyspeptic and intestinal symptoms—diarrhea, constipation, flatulence, anorexia, qualitative and quantitative dyspepsia.
4. Anemic—hypochromic type (achlorhydria).
5. Hemorrhagic evidences.
6. Acutely painful variety—often simulating perforation of a viscus. But he also warns that only in clear-cut cases have gastroscopic findings and the clinical picture been absolutely related.

Eusterman (10) has lately surveyed the question of gastritis from the clinical standpoint, with laudable conservatism. He rightfully insists that acute forms of gastritis due to ingestion of poisonous substances, phlegmonous gastritis, syphilitic and anemic (pernicious and hypochromic) gastritis have long been recognized. Secondary forms, such as found associated with hepatic, cardiac, and renal diseases, diabetes, tuberculosis and other conditions should not be confused with primary gastritis, although pathologically they may show similar congestive, atrophic, hypertrophic erosive, hemorrhagic or ulcerative changes. He then lists ten cases of primary gastritis from which tissue was removed at time of operation. All of these cases had had a positive roentgen diagnosis of some gastric lesion and had been assumed clinically to be ulcer (5), cancer (3), tumor (1) and polyp (1). In nine cases the pathologic diagnosis was some form of gastritis and in one case duodenitis. The symptoms varied somewhat, but in order of frequency were about as follows: Vomiting, nausea, various degrees of epigastric distress, fullness, or pain, (usually at intervals after meals and occasionally with food relief, loss of weight, anorexia, sour stomach, flatulence and weakness.

Henning (11), Von Bergman (12), Korbach (13), Schloss (14) and many others have written in about the same way concerning symptomatology. There seems to be a certain uniformity in their clinical observations. All agree that the so-called pyloric syndrome may be activated by the more severe grades of gastritis. For the less severe grades of gastritis apparently some type of epigastric distress, either immediately following or long after a meal with or without food relief, is expected. In more chronic forms, continuous distress is more likely. Nausea, vomiting, and some evidence of bleeding are quite common, together with anorexia and possibly loss of weight. These symptoms may be accompanied by pyrosis or intestinal symptoms of flatulence, diarrhea or constipation. Most of the authors mention the lack of any localizing findings on physical examination of the abdomen. That is, there is seldom a point of maximum tenderness, the distress being rather diffuse in epigastrium or at least somewhere above the navel.

Our material is composed of 375 gastroscopies, among which 112 individual diagnoses of primary gastritis were made.

All cases in which gastritis was seen to be a condition secondary to, or at least accompanying, other disease were eliminated. Consequently no cases of duodenal ulcer, gastric ulcer, carcinoma, pernicious anemia or gastric operation were included. Although there may be, and usually is, some type of gastritis present with most of these pathologic states, the major signs and symptoms would be presumptively those of the primary condition. We are attempting, in the first place, to determine whether or not gastritis produces symptoms, and if so, whether they are sufficiently peculiar to the condition to have diagnostic value.

In our gastroscopic diagnosis we have followed the simple classification of Schindler (1): superficial catarrhal gastritis; atrophic gastritis and hypertrophic gastritis. We have found, as he pointed out, that the first two conditions seem to be related inasmuch as some cases showed evidences of superficial gastritis together with atrophic changes. In the hypertrophic group various forms were recognized as hemorrhagic, ulcerative, erosive and exudative.

The criteria for superficial gastritis are excess of mucous secretion, usually with flecks adherent to the membrane, together with evidences of congestion, small hemorrhages, occasional edema and hypersecretion. In atrophic gastritis, the mucosa is recognized as being thinner, with visible blood vessels and grey or green-gray areas. In hypertrophic gastritis the mucosa is more red than normal, thicker, with irregular granular, cobblestone, mosaic or pavement appearance, and showing usually also hemorrhagic areas, erosions, ulcerations, or exudate. The superficial and hypertrophic forms tended to have hypermotility or increased activity (contractures or spasms), intolerance to air and other evidences of increased gastric irritability.

The symptomatology of superficial catarrhal gastritis is apparently that of pain immediately after meals, either not relieved by food or aggravated by it. The history is likely to be of short duration and the patients are young (20-40). The X-ray of the GI tract is usually negative, as is the physical examination.

Two cases may be briefly mentioned indicating modification of this type of case. The first is that of an alcoholic with a very typical "ulcer" history over a

long period of time with repeated attacks of hematemesis. The mucosa was markedly congested with great excess of mucus. The other was a young woman with nausea and vomiting as the outstanding symptoms, and was found to have discrete aphthous lesions in the antrum region. These disappeared and the mucosa returned to a normal appearance in about five weeks.

In addition to neuter catarrhal and exudative changes, in many cases atrophy of the mucosa was seen and patients showing such changes have longer duration of history and are of a somewhat older age group (40-60). Their stories are pretty generally that of constant "indigestion," pain of dull character and diffuse upper abdominal location, sour stomach, gas and belching. They have had occasional temporary relief by change of diet. Sore mouth or dysphagia often initiated the more acute exacerbations. X-ray examination in these patients is uniformly negative.

It is a question whether these patients have a primary atrophic mucosa which is so easily irritated that it is subject to repeated acute inflammatory reactions, or whether as a result of such recurrent insults the mucosa finally becomes atrophic. In some patients, who complain that their stomachs have always given them trouble, the first idea is probably correct. We need not discuss whether they were born with a constitutionally defective mucosa, or whether it became so in very early life as a result of childhood infection (Faber (8)). In other patients the history is more limited in time, and more definite as to onset of symptoms, so that one may be allowed to predicate the second of the above theories, which is, in fact, the opinion of most gastroscopists in this matter.

ATROPHIC GASTRITIS

The symptomatology of chronic atrophic gastritis is that of upper abdominal discomfort of a pressure type, often called gas by the patient and accompanied by belching, nausea and vomiting. The distress comes on immediately post cibum and is definitely not relieved by food or medicine taken. Loss of appetite with loss of weight and anemia is often present. Sore mouth or tongue is frequent. These patients suggest the possibilities of malignancy or pernicious anemia. Almost without exception there is a complete absence of HCl in gastric secretion. The age group is again somewhat older (40-60) and the duration of symptoms is generally long (10 years or "all the life"), persistent and constant.

It is at times doubtful whether or not some of the cases mentioned in the previous paragraph should be included under the classification of atrophic gastritis with acute exacerbations, in which case the history is at least over a period, intermittent and the symptoms are somewhat sharper as to painful experiences. Then there are a few patients seen with atrophic mucosa, complete achlorhydria to histamine, who never had had any gastric complaints. The mucosa is certainly atrophic, but is it gastritis? At any rate, a sufficient number of patients with atrophy of the gastric mucosa are seen, with or without more acute inflammatory changes who do have the symptoms mentioned above so that a fairly clear concept of atrophic gastritis has been acquired.

HYPERTROPHIC GASTRITIS

In this group the symptoms are very frequently those characteristic of the ulcer syndrome. But on

close questioning, the patients usually complain that they have distress immediately on eating as well as sometime afterwards, and food or alkali case is not invariable. Many are simply not relieved by food or soda and a few are aggravated thereby. The pain is not discretely circumscribed, does not radiate and rarely occurs at night, contrasted with continuous discomfort of atrophic gastritis; there is periodicity or remissions in the hypertrophic forms, but the total duration of symptoms is not as long. Nausea and vomiting, with relief by vomiting, are much more prevalent than in the ulcer group.

Vomiting in gastritis is the reaction of an intensely and generally irritated mucosa and hence accompanied by pain, nausea and retching, comes soon after meals and gives relief. Vomiting in ulcer is usually to relieve retention caused by obstructive inflammation, scar or spasm at or near the pylorus.

The age range is wide (20-60 years). The acid values are quite variable, some achylia, most hyperacid, and many normal or anacid. The X-ray gastric study usually results in a diagnosis of some irregularities of ulcer type, either single or multiple; some have been diagnosed gastritis when the mucosal relief seemed characteristic. Occasionally a single niche characteristic of gastric ulcer is described, which when viewed gastroscopically is seen to be only one of multiple ulcerations. The radiologist often indicated hyper-rugation and many times found the stomach entirely negative.

The impression is very strong that the time spent in carefully developing, classifying and analyzing many so-called ulcer histories will be rewarded. The tendency to accept the patient's original story at its face value or even to simplify it in terms of conventional forms is too prevalent. When a patient says that he has pain after meals, so well drilled is the historian in "ulcer phraseology" that he many times assumes "food case" without asking. Our experience has been that if the patient be explicitly quizzed on the exact relationship of his distress and means he has taken for his comfort, that a deviation from the classical form will be elicited which will indicate at least the probability of a diagnosis other than ulcer. When, after very careful questioning, the story seems to be that usually associated with ulcer—namely the food-pain-food-case sequence—the gastroscopic examination has revealed the ulcerative form of gastritis, or more rarely hypertrophic mucosa with rather deep sub-mucosal hemorrhages. These cases have not been found as commonly, however, as the type showing hypertrophic changes with exudation, superficial hemorrhages and erosions, which give the histories as analyzed above. There are, however, some cases whose history is modified from that of true ulcer, as suggested above, but in whom a typical round or peptic ulcer without generalized gastritis is found on gastroscopic examination; which emphasizes the necessity for such examination in all patients with any sort of gastric complaints in order that a correct diagnosis may be made.

In order that a control group might be contrasted, the records of patients in whom negative or normal gastroscopic findings were recorded were examined. Some of these examinations were done because the clinician wished to eliminate stomach as possible source of anemia, because of laboratory report of blood in stool, or for some other reason, when no gastric

history at all was present. In other cases recorded as normal a diagnosis of some other intra-abdominal disease was subsequently made. These patients were eliminated from present consideration. The residual cases were almost without exception psychoneurotic individuals with innumerable somatic complaints, of which the gastric symptoms were only a part. Several had migraine, some were air-swallowers, a few had pylorospasm, some with history of vomiting and some with a slight degree of cardiospasm. But there was never an unequivocal history of only gastric disorder. The reference for gastroscopic examination was usually made by the clinician in full recognition of the functional character of the complaint, but because he wished a definite opinion upon which to base his discussion of negative findings with the patient. The essential fact is, therefore, that the history of the patient whose gastric mucosa is found to be normal is not likely to be confused with that of one showing definite changes. He either has no gastric symptoms at all, or such gastro-intestinal symptoms as he does present are merely a part of a general psychoneurotic galaxy at the least explicable by globus, aerophagia, cardiospasm, pylorospasm or spastic bowel disturbances. An occasional patient with a well developed psychoneurosis is found by gastroscopy to have an atrophic gastric mucosa; just what the relationship is, is doubtful. Both Schindler (15) and (Moutier (6) have commented upon this condition.

SUMMARY

Superficial Catarrhal Gastritis occurs in young people, has a short history characterized by epigastric distress immediately on eating, not relieved by further food or alkali ingestion. This type of gastritis, if subject to frequent exacerbations, probably results in permanent atrophic changes and eventually occasions the symptoms of chronic atrophic gastritis.

In well established *atrophic gastritis* the history is of persistent, constant upper abdominal distress of pressure type, not relieved by food or alkali, with anorexia and nausea, and occasional vomiting. The duration is many years. The patients are in the 4th, 5th and 6th decade, and have often lost weight and become anemic, hence to be differentiated from malignancy or pernicious anemia; they may be subject to acute exacerbations, often with sore mouth and tongue.

The *hypertrophic gastric* patients have epigastric pain, either immediately post cibum or at an interval thereafter, sometimes with food or alkali relief, but more often being not relieved or aggravated thereby and with a pronounced tendency to nausea and vomiting, the latter giving relief. The history is of long duration with periods of remission. The type of pain is burning or gnawing, or a dull ache, but does not radiate nor occur at night and is diffuse in upper abdomen.

The X-ray findings in the superficial and atrophic

forms of gastritis are negative, while in the hypertrophic forms they are equivocal, indeterminate, or show ulcer niche types of defects, often multiple. Occasionally the diagnosis of gastritis has been made, usually in the hypertrophic type by changes in mucosal pattern.

There is no diagnostic aid from the evaluation of degrees of acidity of the gastric secretions in the superficial forms; the atrophic forms are distinctly achlorhydric, while the hypertrophic type may be achylie, anacid, hypo or hyper-acid, with a preponderant number of the last.

Evidences of gastric hemorrhage, either hematemesis, or melena has been found with all forms of gastritis, possibly more frequently with the hypertrophic types. We agree with Benedict therefore, that hemorrhagic evidences are strongly indicative of gastritis if another responsible lesion has not been demonstrated.

CONCLUSION

The impressions gained from a survey of the literature previously given seems to be borne out by this study. That is, any stable patient without psychoneurotic stigmata who has a definite consistent story of some type of gastric distress and in whom neither X-ray nor physical examination has revealed characteristic findings, may be given a presumptive diagnosis of gastritis. Gastroscopy in this type of patient is definitely indicated, and if done, will probably reveal some change of the gastric mucosa. If the history has been continuous over a considerable period and has consisted of dull, heavy pressure discomfort, unrelieved by anything he has been able to do, resulting in anorexia and loss of weight and anemia, he may be suspected of having the atrophic form, particularly if he has achlorhydria. If the history has been of long duration but with periodic remissions, characterized by pain occurring sometime in the digestive cycle, either not relieved or aggravated by food and relieved by vomiting, non-radiating and diffuse, he may be suffering from the hypertrophic form of gastritis, particularly if X-ray reports have been indeterminate, negative or uncertain. If the history has been quite typical for ulcer, but the X-ray examination has been negative or shown questionable defects, he may have a gastric ulcer or ulcerative, erosive or hemorrhagic gastritis. Finally, critical judgment of the above observations and analyses leads inevitably to the opinion that gastroscopy should be employed as an adjunctive method of diagnosis of gastric conditions. Since submitting this article for publication, a total of 475 gastroscopic examinations has been done, with a diagnosis of primary gastritis made in 134 incidents. A careful survey of these patients, as to symptomatology, has not changed the opinions which follow in any important particular.

Esophageal Varices in Portal Hypertension*

Pathogenesis and Diagnosis by Roentgenography

By

MILTON PLOTZ, M.D., F.A.C.P.†

and

NATHANIEL E. REICH, M.D.‡

BROOKLYN, NEW YORK

IN the consideration of the patient who has been vomiting blood, only too often is scant attention paid to the possibility of the hematemesis being caused by lesions other than bleeding peptic ulcer. Lesions of the esophagus ranging from ulcer to cancer, gastritis, gastric carcinoma, gall bladder disease, blood dyscrasias, certain acute febrile diseases, and, above all, the group of cases associated with portal hypertension (portal and unclassified hepatic cirrhosis, splenic or portal thrombosis, splenic anemia and Banti's syndrome, schistosomiasis mansoni) may be responsible for hematemesis. Bulmer (1), noting 67 deaths directly due to gastro-intestinal hemorrhage, found nine that were caused by hepatic cirrhosis or portal thrombosis. Rivers and Wilbur (2) found 4 out of 27 deaths to be due to the same causes and found cirrhosis of the liver or splenic anemia to account for 5.1% of 668 cases which were admitted to the Mayo Clinic with hematemesis as chief complaint. Viewed from the standpoint of the cirrhosis, the importance of hematemesis becomes clear when it is realized that about 25% of patients with this disease have hemorrhages (3). McIndoe (4), analyzing 26 cases of advanced cirrhosis, found that 50% died of gastro-intestinal hemorrhage. Blumenau (5) found that 19% of 126 cases of portal cirrhosis died from vascular lesions. Since the life expectancy of the average patient with portal cirrhosis has been increased (4) since the introduction of newer medical treatments such as the use of mercurial diuretics and high carbohydrate diets, there has been a striking increase in fatal lesions of the vascular tree. There is every reason to expect this trend to continue.

PATHOGENESIS

A brief consideration of the pathogenesis of varices of the esophagus is essential for a better understanding of their production and early diagnosis. In portal hypertension (6), blood which normally flows freely through the portal veins is dammed back into its tributaries and through new or little used collaterals into the systemic circulation. The anastomosis in the lower third of the esophagus is composed, on the portal side, of vessels which are found in the cardiac end of the stomach. In turn, these are formed by two veins or groups of veins. Most important is the coronary vein (may be multiple) which normally runs along the lesser curvature of the stomach, anastomoses with the pyloric veins and enters into the portal vein directly behind the superior part of the duodenum. The

coronary vein drains the lower part of the esophagus, the cardia, and anterior and posterior surfaces of the stomach.

The second group consists of the left gastroepiploic vein and the short gastric veins which run between the spleen and the superior half of the greater curvature, anastomosing with branches of the coronary vein and joining in the formation of a cardiac rete or plexus of veins. It is this second group of vessels which may primarily involve in splenic disease without notable portal obstruction. The diagram (Fig. 1) illustrates these anastomoses and indicates as well the connections between the esophageal network and the systemic circulation. It will be noted that for a short distance just above the cardia, there exist small longitudinal venules with cross anastomoses. Above this point is a rich network, the usual location of clinically significant varices.

At the cardia, the veins are strongly supported by a thick muscularis interna and an adherent mucosa bound down to the submucosa by strong interlacing fibers and connective tissue. Above this point, however, the rich venous anastomosis of the submucosa is very poorly supported by loose connective tissue, hence an ideal site for the formation of varicosities, especially with the superimposed aspirating effect of negative intrathoracic pressure.

Since medical treatment has been essentially unsuccessful in the management of the bleeding of portal hypertension, surgical intervention based on early diagnosis offers the most hope and will probably often be the method of choice. As McIndoe (4), Mandel and Marcus, Kegaries (6), Walters (7), Rousselot (8) and others have indicated, the following surgical procedures have been recommended at one time or another. 1. Cauterization: a direct attack made through the esophagoscope which has met with little success. 2. Ligation of the coronary veins: theoretically excellent and sometimes quite simple but not always possible. 3. Ligation of the vasa brevia, may be combined with the second or fourth method or both. Failure to ligate these veins properly may account for recurrent hemorrhage. 4. Splenectomy about which numerous articles have been written. It is said to reduce the portal blood by 20% (9). Burton-Opitz (10) found that in the dog 21% of the portal blood comes from the spleen. Simonds (11) has outlined the objections to splenectomy. 5. Increase of collateral circulation: production of Eck fistula (not feasible clinically) or the Talma-Morrison operation. The latter, occasionally brilliantly successful, has usually not been satisfactory. It may be performed after completing ligation of the coronary veins.

There is reason to believe, therefore, that surgical

‡Clinical Assistant Physician.

Intervention can offer some hope of increasing the comfort and prolonging the life of patients with esophageal varices but progress will be difficult until earlier diagnosis is made possible. X-ray diagnosis has recently received much attention in the literature and we have found it to be extremely useful in the early establishment of the presence of esophageal varices.

X-RAY VISUALIZATION

X-ray observations vary greatly with the anatomical stage of the disease. Oppenheimer (12), in a recent excellent comprehensive study of a large series, points out three groups: 1. The early stage, marked by a slight and diffuse venous congestion, resulting in moderate broadening of the rugae of the lower part of the esophagus. 2. Beginning dilatation of larger individual veins which emerge from the submucosa into the mucosal relief, marked by small rounded defects seen in the relief of the lower fifth of the tube. 3. Generalized enlargement of numerous veins which encroach upon the mucosa in which period the typical vermiform negative shadows predominate.

Since varices, as Oppenheimer points out, are compressible anatomic formations, various factors may influence their filling. Definite variations in their character are produced by peristalsis, especially stripping, and by mechanical pressure as of a large bolus or tumor formation. These factors force blood into the lower vessels. In early portal congestion, the blood can still pass into the abdominal veins. Later, it is expressed from the upper varices into the lower ones, overfilling the latter.

At the beginning, this mechanism makes varices invisible and the early congestion is frequently recognizable clinically on positive X-ray signs only. In advanced stages, only a part of the whole extent is visualized and roentgenograms generally do no more

Fig. 1. Formation of varices in the esophagus and cardia. Note that the upper third of the stomach and esophagus has been exposed by removal of the anterior wall (Modified from Brdiczka and Tschakert (12B) and Kegaries (6)).

Fig. 2. X-ray of Barium-filled Esophagus illustrating Esophageal Varices.

than confirm the clinical diagnosis. It is necessary, therefore, to demonstrate the mucosal relief when unaltered by peristalsis or mechanical compression.

Optimal visualization, according to Oppenheimer, depends upon several factors. The films should be exposed during forced inspiration as esophageal varices form best at this moment. They are best seen during the short interval between swallowing and stripping. The retardation of the passage through the esophagus varies between a few seconds in early congestion and several hours in terminal stages with superimposed cardiospasm. It is often due only to mechanical obstruction by the varicose mass but it must be remembered that in both the early and terminal stages various functional disturbances affecting the cardia, such as cardiospasm, also produce esophageal stasis. It is important to differentiate esophageal carcinoma which may occasionally produce a similar X-ray picture, by careful history, physical examination and, if necessary, by esophagoscopy. As will be pointed out later, the distinction can also be made on purely roentgenological grounds.

X-ray visualization has distinct advantages over direct visualization through the esophagoscope for several reasons. Esophagoscopy (13) is a highly specialized procedure to be attempted only by those with adequate experience. It may not even be available in smaller institutions and it is definitely not an office procedure. The possibility of direct trauma to a

varix with fatal hemorrhage or perforation of the esophageal wall is an ever-present danger; or, as previously described, mechanical pressure may express blood from upper varices to lower ones, overfilling the latter to the bursting point. In an earlier stage, blood may be expressed from the venous bed with temporary disappearance of the affected area and consequently may pass unnoticed. The production of inflammatory complications, from a transient throat soreness to an acute esophagitis or even mediastinitis is possible. Finally, the consideration of refusal of an operative procedure on the part of the patient may be decisive.

On the other hand, roentgenograms are usually available everywhere, present the typical appearances, are simple of application and not attendant with any of the previously mentioned objections.

The differential diagnosis by X-ray includes first, the differentiation from food particles. When the latter cast suspicious shadows, repetition of the examination after thorough evacuation of the esophagus will fail to reveal lesions. The presence of polypi can be ruled by the rapid passage of the barium and the absence of obstruction in proportion to the degree of protrusion. New growth may be ruled out by the softness of the esophageal wall and its elasticity which appears unimpaired. There is not enough constriction and irregularity of the wall to resemble syphilis. Finally, cardiospasm may be ruled out by the absence of the smooth esophageal wall so characteristic of that condition.

TYPICAL CASE HISTORY

M. M., 35, male, American of Italian descent, was admitted to the Kings County Hospital, vomiting blood. He had had a continuous hematemesis since three that morning when he had been awakened by nausea and a cold sweat. Gastro-intestinal history: no constipation, diarrhea, or hemorrhoids. He had been a moderate drinker of spirits for years. One year ago he had been admitted to the hospital for one day for transient abdominal pain. Occasional substernal discomfort, not related to meals or exertion, had troubled him recently. The past history was irrelevant. There had been some dyspnea on exertion for the past two weeks. There was no ankle edema. The patient said that he was an acetylene welder who for three months previously had been working in a closed building, burning out boilers. Masks which were not very efficient had been worn to keep out the fumes, but all the workers complained of nausea and frequently vomited.

Physical examination was negative except for the following points: an icteroid tint to the sclerae, upper abdomen spastic. Later a mass was found in the left upper quadrant, believed to be spleen. Laboratory findings: the red blood count varied between 2,120,000 and 2,620,000 and the hemoglobin between 43% and 47%. The white blood count was 5,200 with 78% polymorphs. Coagulation time was 3 minutes, the clot retraction time 22 minutes, the bleeding time 90 seconds. The platelet count was 310,000. The urine was negative. The stool was negative except for occult blood. The sugar tolerance test was normal. The gastric analysis was normal except for very low free acidity. The blood fragility test was normal. An initial tentative diagnosis of bleeding peptic ulcer was made; but this diagnosis, in the light of the gastro-intestinal series, was changed to a diagnosis of bleeding esophageal varices, secondary to splenic disease, either primary splenic vein thrombosis or Banti's syndrome.

Gastro-intestinal series (14): There was a normal pattern of the mucosa of the esophagus in its upper third. The straight rugae of the proximal third blended with small oval and round snail-like protrusions (see Figs. 2, 3) encroaching upon the lumen of the remainder of the

Fig. 3. Esophogram. Same case.

esophagus. These protrusions were more pronounced on the anterior aspect of the wall and apparently rested on broad bases. The lumen of the esophagus was consequently widened in this area. An oblong shadow of the mediastinum compared favorably with widening of the mediastinum and there was a typical dilatation of the azygos vein not encountered in any other condition, as described by Grilli (15).

Course: The patient was given several small transfusions and had no gastro-intestinal complaints. However, within two weeks of admission he began to complain bitterly of constant dull pain extending from the left costovertebral angle to the umbilicus in front. The spleen was definitely enlarged to about six centimeters below the costal margin but after the subcutaneous injection of five minims of adrenalin it shrank, until within fifteen minutes, it was only just palpable. There was a questionable small amount of ascites. A diagnosis of Banti's disease was made finally and the patient was transferred to the surgical ward. Splenectomy was performed by Dr. Henry Louria six weeks after admission to the hospital. The spleen was six times normal size and firmly adherent to the under surface of the diaphragm. It was quite firm, pale in color, with a granular surface. The vessels of the pedicle were enlarged and tortuous but there was no evidence of thrombosis. The liver was half normal size, the surface pale and irregular, characteristic of the hobnail type of cirrhosis. The patient did well until two days after the operation when he became drowsy and his temperature rose to 102 degrees. The blood urea was 90 and the blood sugar 120. On the following day the patient lapsed into coma and had several generalized convulsions. There was a bilateral Babinski. The patient expired on the evening of the third postoperative day. A post-mortem examination, limited to

the abdomen, was performed and showed congestion of the pancreas, adrenal, and kidneys. The ureters and urinary bladder were normal. The gall bladder was contracted and its coat thickened. The liver has already been described. The gastro-intestinal tract was negative except for ruptured esophageal varices, the rupture being 4 cm. above the cardia. The pathological histological findings, to be reported elsewhere in detail, were those of portal cirrhosis with congestive splenomegaly.

CONCLUSIONS

1. The value of esophagrams in the demonstration

of esophageal varices, and therefore in the early diagnosis of portal hypertension, is emphasized.

2. Early diagnosis is essential if surgical intervention is to be successful.

3. A case of fatal hematemesis from ruptured esophageal varices secondary to portal cirrhosis is reported with operative and autopsy findings.

Our thanks are due to the X-ray staff under the direction of Dr. R. A. Rendich and to Dr. Ehrenpreis for preparation of the films and help in interpretation.

The Gastro Pump

By

SAMSON A. SELEY, M.D.
BROOKLYN, NEW YORK

THE following is a description of a simple apparatus first devised to facilitate gastric extraction and lavage in the Gastro-intestinal Clinic of the Greenpoint Hospital. The members of the clinic call it the "Gastro-Pump."

Besides gastric lavage we have found this apparatus useful for duodenal intubation, for Lyons-Meltzer drainage, for withdrawal of ascitic fluid in abdominal paracentesis, for irrigation of the urinary bladder, chest or other organs.

Description of apparatus: The "Gastro-Pump" consists of two graduate quart bottles with rubber stoppers, each having two openings. Bottle A (see diagram) has a glass tube no. (2) connected with a valve bulb no. (1). Pressure on bulb no. (1) forces air into the bottle, forcing fluid out of the bottle into glass tube no. (3). There are two stopcocks, nos. (4 and 6) connected to a Y tube no. (5). A Levine tube is inserted into the stomach and connected with the Y tube. When stopcock no. (6) is closed and stopcock no. (4) is open, pressure on bulb no. (1) will force fluid into the stomach. When the stomach is filled with sufficient fluid, stopcock no. (4) is closed and stopcock no. (6) is opened. Pressure now on bulb no. (9) will create a vacuum in bottle B and the stomach will be rapidly emptied.

Technique for gastric extraction: At 5 p. m. the day before, the patient is advised to eat a few raisins. At 9 a. m. the patient is permitted to eat a light breakfast including a roll with poppy seeds. He is instructed not to eat after 9 a. m., but may drink water. At 2 p. m. he is given 90 ccs. of 7% alcohol and twenty

minutes later the Levine tube is inserted into the stomach and connected with Y tube no. (5). Stopcock no. (4) is closed and stopcock no. (6) is opened. Pressure on bulb no. (9) causes a vacuum in bottle B which quickly empties the stomach contents into bottle B. The quantity is immediately noted by the graduation markings on bottle B. An amount greater than 90 ccs. indicates either gastric retention or hypersecretion. If poppy seeds are seen in the bottle there is six hour retention, and the presence of raisins indicates twenty-four hour retention. The contents of bottle B may then be removed for further analysis.

Technique for gastric lavage: Bottle A is filled with

Fig. 1

Fig. 2

warm water. After the Levine tube has been inserted into the stomach, stopcock no. (4) is opened and stopcock no. (6) is closed. Pressure on bulb no. (1) forces the water into the stomach as slowly or rapidly as desired. When sufficient water has been forced into the stomach, stopcock no. (4) is closed and stopcock no. (6) is opened. Pressure on bulb no. (9) draws the stomach contents into bottle B. Bottle A may then be filled with solution of sodium bicarb or other medication desired and the procedure repeated until contents withdrawn into bottle B are perfectly clear.

Technique for Lyons-Meltzer Duodenal intubation: A Rehfuß or Einhorn tube or Twiss or Weiss tube or whatever tube is preferred, is passed into the stomach and connected with Y tube no. (5). The patient is placed on his right side. Bottle A is filled with cold water. At intervals of about five to ten minutes by opening stopcock no. (4) and closing stopcock no. (6),

about two ounces of cold water are forced into the stomach. This increases peristalsis and facilitates the passage of the bucket into the duodenum. When water is not being forced into the stomach, stopcock no. (4) is closed and stopcock no. (6) is opened, allowing drainage into bottle B. With a little experience one may recognize the different appearance of duodenal contents from stomach contents. When duodenal contents appear in bottle A, the water is emptied out of bottle A and 100 ccs. of 25% magnesium sulphate is placed into bottle A. This is forced into the duodenum about one ounce at a time to avoid nausea. If there is a question about whether the bucket is in the duodenum and fluoroscopic investigation is not possible to determine position of bucket, a few drops of Toepfer's solution may be placed in bottle B. If stomach contents are being drained the free hydrochloric acid will turn the Toepfer's solution red. Duodenal contents will change the red color to yellow.

Fractions A, B, and C usually can be seen in different layers in bottle B and finally when the clear oil like liver bile begins to appear, it can be easily seen coming through the glass tube into bottle B.

Technique for abdominal paracentesis: After having the patient urinate, a trocar is inserted into the abdominal cavity at the point desired. The trocar is connected with a rubber tube to Y tube no. (5). Stopcock no. (6) is opened and pressure on bulb no. (9) draws the abdominal fluid into bottle B. By closing stopcock no. (6) partially the rate of flow of ascitic fluid may be controlled and sudden splanchnic dilation avoided.

Technique for irrigation of urinary bladder, chest cavity or other organs: Insert Catheter into urinary bladder and connect with Y tube no. (5). Draw out urine as with gastric lavage. Inject boric acid or other solution through bottle A. Alternate injection with withdrawal.

Clinical Course of Chronic Ulcerative Colitis

(Based on 7662 Proctoscopy Examinations)

By

M. H. STREICHER, M.D.*

INTRODUCTION

ULCERATIVE colitis remains a difficult disease to manage, difficult to get patient well and to prevent relapses. I have been engaged in the study of these cases and was interested in following them over a period of time with the hope that some plan of treatment could be found for improving the percentages of cures.

Yeomans, Bassler and Lynch (1, 2, 3) consider the disease to be of infectious origin; Thorlakson (4), Hurst (5) and Einhorn (6) refer to this entity as being primarily due to bacillus of dysentery. In 1924, Logan, Buie and Borgen (7, 8, 9) stated that ulcerative colitis was of bacterial origin and Borgen (1924) further reported the diplostreptococcus to be the specific etiologic factor. In 1926, Streicher and Kaplan (10) made clinical and experimental studies on ulcera-

tive colitis and reported that all bacteria present in the colon during the course of this disease were responsible causative factors (J. A. M. A., 1930).

It is quite obvious that in the presence of severe infection with loss in weight, diarrhea, cramping in the abdomen and loss of body fluids the individual's nutritional reserves are rapidly depleted and remain subnormal. Indeed, the nutritional factors favoring wound healing may be entirely absent.

METHOD OF STUDY

During the past eleven years we have observed 570 cases of chronic ulcerative colitis. This group may be classified as:

- Those observed once during initial proctoscopic examination
- Those treated and classified as "improved"
- Those treated and classified as "cured"
- Those treated without improvement
- Those who were unimproved and died.

*From the Research and Educational Hospital, University of Illinois, College of Medicine, and Grant Hospital, Chicago, Illinois.

TABLE I
Data showing number of patients studied and years of "follow up"

Type of Patients	Years of "Follow Up"								Average of Group
	*1	2	3	4	*5	6	7	8	
Improved	21	18	19	19	17	8	16	23	141
Cured	0	0	3	2	6	3	5	6	25
Unimproved	15	10	7	4	2	3	2	2	45
Died	0	2	0	2	1	0	0	1	6
Total Average	36	30	29	27	26	14	23	32	217*

*Explanatory Note: In the improved group 21 cases were studied for one year and 17 cases were studied for five years; in the unimproved group 15 cases were studied for one year and two cases were followed for five years. Discussion of the groups will follow later.

Of the entire group 217 patients were observed a year or longer. These cases were observed regularly once a week or once in two weeks for a period varying from one to eight years. A standard diet was prescribed, and in addition to some medications given during the onset of the course of the disease, polyvalent vaccine was injected at weekly intervals. At the termination of each year the patient was reprotoctoscoped and observed for any changes or complications. Stool examinations were made on numerous occasions to rule out amebic infestations and to correlate the proctoscopic findings. In many instances bacteriologic studies were made of the material removed through the proctoscope during subsequent reexaminations.

CLINICAL COURSE

Unlike other gastro-intestinal lesions, the physician cannot always rely on the symptoms of this disease as an accurate index of the healing of the ulcerations in the colon. While it is probably true that the curtailment of diarrhea, the decrease of the amount of blood and pus in the stool, and the alleviation of pain in the abdomen are very helpful in determining the progress of the patient, the real criterion certainly lies in the pathologic view of the mucosa of the colon through the proctoscope. While reexamination is the method of choice one must not lose sight of the fact that at times proctoscopic examinations repeated too often, are responsible for recurrent attacks of diarrhea. These attacks run the clinical course of a "remission attack."

Exacerbations occur during acute respiratory infections or during reactivation of focal infection, but recurrences ensue less often, at longer intervals and are less severe after the patient has been on proper management. At present the general impression is that the longer the patient with ulcerative colitis remains on controlled management plus vaccination, the greater the interval of absence of recurrence after treatment is discontinued.

In Table I we are showing the number of cases observed in each group during each year.

In the course of our studies various changes were noted in these patients on proctoscopic reexamination; during these reexaminations bacteriologic cultures were made to correlate the proctoscopic findings in the colon. Whenever possible post-mortems were obtained

of the patients who have died and the findings are recorded.

In Table II we are showing the various changes noted during a period of eight years. The changes noted are again classified by groups.

In the course of our studies we have observed that about 80% of the patients are either improved or cured in due time depending on the clinical course of the case. Less than 3% meet with a mortality. The remaining 17% are unimproved or meet with a com-

TABLE II
Data showing "follow up" studies by proctoscopic, bacteriologic and post-mortem findings

Type of Patients	Proctoscopic Findings	Bacteriologic Findings	Post Mortem Changes
Improved	Fewer ulcers are seen; they are not deep, healing evident. Less edema of colon.	Fewer B. Coli per field — and fewer. Diplostreptococci Staphylococci still present. Hemolytic strept. absent. B. acidilactici present.	
Cured	No ulcerations. No edema. Evidence of healed ulcers.	B. Coli — Strept. (Viridans) ratio approaches normal limits. Hemolytic strept. absent. B. acidilactici absent.	
Unimproved	Ulcers numerous, extensive, deep. Miliary abscesses noted. Edema extensive. Marked scarring and fibrosis. Lumen narrow.	B. Coli count exagg. Strept. Viridans count increased. Staphyl. present always. Hemolytic Strept. present often.	
Died			Gross The ulcers in colon $\frac{1}{4}$ to $\frac{3}{4}$ inches wide and 3 mm. deep. Ulcers penetrate to serosa. Mesenteric glands swollen & soft. Micro: Mucosa replaced by granulation tissue, no giant cells, no ameba, necrosis of muscle layer evident.

plication which terminates fatally. It is therefore that we now wish to refer to a discussion on the complications met with during the clinical course of chronic ulcerative colitis.

COMPLICATIONS

The most common complications that we have observed in the colon are polyposis, stenosis, perforation, malignancy, and perirectal abscess. There are many other interesting and serious complications that may occur in ulcerative colitis, but they are not in the colon per se—such as endocarditis, dermatitis, nephritis, arthritis, renal abscess, cystitis and osteomyelitis. In Table III we show the complications noted and the percentage of occurrence.

TABLE III

Data showing type of complications observed and percentage of occurrence in 217 cases

Name of Complication	Number of Cases	Per Cent	Remarks
Polyposis	21	9.7	Observed mostly in Recto-Sigmoid.
Stenosis	16	7.4	In various segments of colon.
Perforation	3	1.2	Two in sigmoid, one in cecum.
Malignancy	3	1.2	Usually very malignant.
Perirectal abscess	1	.4	Uncommon.

Polyposis the most common complication is of interest because it is recognized when the patient is definitely improved (Rankin, Borgen and Buie, W. B. Saunders Co., 1935). The percentage of polyposis of the colon in chronic ulcerative colitis is about 10.5% while the percentage of polyposis without ulcerative colitis is 4%. It is important to remember that a polyp of the colon may become malignant (Mayo and Wakefield) 1936, J. A. M. A. The malignant disease is usually of the rapid, early fatal type and frequently occurring in the form of multiple carcinomas of a high grade of malignancy (Broders, 1935).

No where do we depend so much upon barium enema (roentgenoscopy) for diagnosis as we do in stenosis following ulcerative colitis because we cannot observe stenosis situated above 30 cm. with the sigmoidoscope.

PLAN OF MANAGEMENT

In the main the management resolves itself into the treatment of:

a. A group of patients of chronic ulcerative colitis who are able to eat a well balanced, basal plus diet, of low residue, high vitamin and high calory. When the acute onset of the disease subsides these patients are advised to gradually rid themselves of possible foci of infections and they are given vaccines to protect them

selves against recurrences of acute attacks. Attention along symptomatic lines is given.

b. There is another group of patients with ulcerative colitis who exhibit definite nutritional disturbances. These represent cases with a low plasma proteins, a low serum calcium, a low total base, and possibly an inverted albumin-globulin ratio. In the management of these types it is of course essential to supply fluids, liver extract, blood transfusions and other supportive measures such as Vitamin C to control hemorrhage from the colon. Later when the patient is recovered sufficiently so that healing may ensue, further treatment may be instituted.

c. Still another group is one of impending complications comprising a very small percentage. It is in this group only that surgical interference may be indicated.

DISCUSSION

It is most unfortunate that one cannot follow-up all cases observed. In general the average ambulatory ease of chronic ulcerative colitis improves on systematic management within six months or a year.

The so-called cured case usually represents prolonged care plus a very cooperative patient. The proctoscopic view of the colons of these patients is amazingly normal.

The patients that have caused us much concern are the unimproved cases. These gradually become worse regardless of the method of approach. One hesitates to remove foci of infections in these patients too rapidly because with each focal elimination there has always occurred a severe recurrent attack. As a basis for this lack of progress in these types is the presence of a hemolytic streptococcus in the cultures from the colons of these patients.

So much has been written on the surgical management of chronic ulcerative colitis that it seems desirable to mention it here briefly. Rankin said that when medical measures have failed in any advanced case, the ease will not lend itself to operation, and if some drainage operation (ileostomy) is undertaken it is with very high risk. Of the seventy ileostomy operations performed, 41 died, 10 showed good results, 2 showed fair results and 17 showed very poor results. In our series of 217 cases surgical interference has been required in three instances.

CONCLUSION

In following these cases we have learned:

1. That bed rest, dietary regime, vaccines and blood transfusions is the management of choice in chronic ulcerative colitis.
2. That proctoscopic reexaminations once yearly aids in the management of these patients.
3. That removal of foci of infections is beneficial.
4. That surgical interference should be reserved only for acute complications.

Factors Which Reduce Gastric Acidity

A Survey of the Problem*

By

FRANKLIN HOLLANDER, Ph.D.†

NEW YORK, NEW YORK

INTRODUCTION

IT is the purpose of this review to discuss the numerous factors which may be responsible for the normal variations in gastric acidity, observed both in clinical practice and in the experimental laboratory. This problem is important because it involves several fundamental physiological processes which still await clarification; and which, once we understand them, may bring to our attention significant differences in the acidity curves associated with various clinical conditions. Furthermore, a physiological method whereby the acidity curve may be lowered significantly, as a therapeutic measure in cases of gastro-duodenal ulceration, is today one of the most pressing clinical problems in the field of gastro-enterology; and it may be that a thorough comprehension of the various factors which normally effect a reduction in gastric acidity will enable us to use one of them for the complete elimination of free acid from the stomach contents by a simple physiological procedure. Above all, however, we are concerned with a critical analysis of the basic physiological principles involved, since their practical application can come only after we have established the scientific foundation on which they rest.

Let us first of all consider the factual manifestations of acidity reduction in the stomach. At the present time, it is widely accepted that the hydrochloric acid secretion is poured into the gastric cavity by the parietal cells, ordinarily at a uniform concentration level of 160-170 mN¹ (Hollander, 1934,a). Examination of ordinary fractional test-meal curves, however, reveals the fact that the curve starts at a very low level after ingestion of the test-meal and then rises considerably, but it rarely goes above 100mN, and practically never attains a value of 150mN. The curve may then remain at the maximum for some time—the duration will vary with the individual subject—after which it will fall off again in a more or less characteristic way. In dogs provided with fundus pouches, the results are ordinarily very similar to the above, as they are also with histamine in both dog and human. Thus, at no time does the acidity in the stomach attain a value at all near that which characterizes the pure parietal secretion. Why is this so? What are the various factors which may be responsible in varying degree for this lowering of the acidity from its normal physiological maximum? Some of these

factors are obvious and unquestionable; most of them, however, are still in the hypothetical stage. The intimate mechanisms which they involve are diverse; variation in the amount of HCl actually poured into the stomach², reduction in acidity by neutralization and dilution—both of these appear to be effective in part. Moreover, some of them may be classified as extra-gastric in origin, whereas others are distinctly intra-gastric. Among the former there are:

- (1) dilution by the test-meal itself,
- (2) both dilution and neutralization by saliva, and
- (3) dilution and neutralization by regurgitated duodenal fluid.

The intra-gastric factors include:

- (4) possible variations in the composition of the parietal secretion itself (variations in the volume-rate of secretion of this fluid will not be considered here),
- (5) reabsorption of HCl, already secreted, by the gastric mucosa,
- (6) dilution by the peptic secretion,
- (7) dilution and neutralization by a distinct dilution secretion, and finally
- (8) the dilution and neutralization effects of mucus secretion from the surface epithelium.

In this review I shall attempt merely to define these several factors and to evaluate them in the light of our present knowledge. Also, I shall point out, wherever possible, what further work must be done in order to clarify present uncertainties, and to extend the information already available. In subsequent reports on this subject, we plan to adduce such additional experimental evidence, and particularly to evaluate the relative importances of these several factors in the composite picture of acidity regulation. Let us now proceed to discuss each of these factors in turn.

DILUTION BY THE TEST-MEAL

Let us consider a Rehfuß series with gruel as the gastric stimulant, wherein the fractional samples withdrawn at quarter hour intervals may continue to give gross evidence of the presence of the test meal for 2 hours or more. Each of these specimens consists in part of mixed gastric secretion and in part of test-meal—the proportions being highly variable and dependent on all sorts of chance conditions. Hence it is apparent that the acidity values as measured by direct titration do not represent the acidity of the gastric juice itself, and the shape of the acidity curve obtained in the usual way is dependent, not only on the secretory characteristics of the individual, but upon the rate of elimination of the test-meal from the stomach—that is, the rapidity and regularity of gastric evacuation. Thus, if we desire to evaluate the gastric acidity,

2. This aspect of the problem (i.e., variation in the rate of secretion of the parietal fluid) is not included in this paper. For an excellent analysis of this factor, see *Wieland, Finegan and Hill (1937)*.

1. Acid concentration in terms of milli-equivalents per liter or milli-normal (mN) is numerically equal to the number of clinical units or degrees of acidity; that is, cc. of 0.1N alkali required to neutralize 100 cc. of gastric juice. In terms of pH, an acidity value of 165 mN corresponds to a pH value of 0.57; in terms of per cent of HCl it is 0.60%.

*This work was supported in part by a grant from the Friedsam Foundation.

Based on an address delivered before the New York Gastro-Enterological Association, April 20, 1937.

†From the Laboratories of the Mount Sinai Hospital, New York City. Submitted December 8, 1937.

uncomplicated by this test-meal dilution factor, it is necessary only that we know the relative amounts of test-meal and digestive fluid present in each specimen. If we divide the observed acidity by the fractional amount of gastric secretion (or, what is the same thing, by one minus the fractional amount of test-meal) the quotient is the acidity corrected for test-meal dilution.

In order to determine the percentage of test-meal present, we must mix with the test-meal a dilution indicator, that is, some substance which lends itself readily to simple and accurate analytical determination in addition to possessing a number of other well defined characteristics. Chief among the substances used in this way are phenolphthalein (Lanz, 1921; Bloomfield and Keefer, 1927) and phenol red (Gorham, 1923; Bulger *et al*, 1928; Wilhelmj *et al*, 1933). Of these investigators, only Bloomfield and Keefer, and Wilhelmj and his coworkers, have employed the dilution indicator specifically for the purpose of correcting the gastric secretory curve for dilution by the test-meal, the former in humans and the latter in dogs. In order to illustrate the changes in magnitude and shape of the acidity curves which may be effected by instituting such a correction for test-meal dilution, let us consider one of the experiments cited by Bloomfield and Keefer, in which 7% alcohol was used as the test-meal and 10 mgm.-% of phenolphthalein as the dilution indicator (Fig. 1). As is evident from the solid line

FIGURE 1

Fig. 1. Gastric acidity curves (human) with and without correction for dilution by the test-meal (50 ml. of 7% alcohol with 10 mgm.-% of phenolphthalein as dilution indicator). Data from: Bloomfield and Keefer. Arch. Int. Med., 37:831, 1926.

curves, both free and total acidities start about 30mN, rise to maxima about 55, and then fall off to the initial values or lower. The concentration of phenolphthalein present in each specimen is recorded at the top of the chart; if we divide each observed acidity by 10-this value respectively, the resulting quotations

10

yield the acidity values as they would be in the absence of the test-meal dilution factor. The curves corresponding to these corrected acidities are given by the broken lines in the figure. It is interesting to note, in this particular case, not only that the first four or five

points are elevated considerably by this correction, but that the entire shape of the curve has undergone a transformation.

Unfortunately, although the principle illustrated by this comparison of uncorrected and corrected acidity curves is sound, we are not able to attach any quantitative significance to these particular observations, because phenolphthalein is inadequate as a dilution indicator. In a recent investigation of this matter (Hollander, Penner and Saltzman, 1937,a) we found that the solubility of the indicator in 7% alcohol, and therefore also in dilute acid solutions, is considerably less than 1 mgm.-%, which is its initial concentration in the test-meal employed by Bloomfield and Keefer. Consequently, a considerable amount of the phenolphthalein is slowly precipitated within the gastric cavity, which completely invalidates the calculations based on its concentration in any one specimen. Similar difficulties obtain with other substances which have been proposed as dilution indicators, with the sole exception of phenol red. At the present time we are investigating the reliability of the latter for this purpose, having already developed a simple method for its quantitative determination which is good to one per cent or better (Hollander, Penner, and Saltzman; 1937,b). Once we are assured of its dependability for these purposes, we shall be in possession of a technique for eliminating completely the influence of test-meal dilution from our studies of the more specifically physiological factors in acidity reduction.

ADMIXTURE OF SALIVA

The influence of salivary admixture with gastric contents was recognized in the earliest practices of gastric intubation. The nature of this influence is two-fold: For one thing, it reduces the gastric acidity by means of a simple dilution effect, the magnitude of which may be considerable. For another, it is generally recognized that the saliva possesses a considerable degree of titratable alkalinity, as may be illustrated by the observations of De Beer and Wilson (1932). These investigators reported a bicarbonate concentration of 55mN and a chloride concentration of 82mN (averages) for the parotid saliva of dogs under pilocarpine stimulation. Similar values have been reported for human salivary secretion. Admixture of such an alkaline fluid with the acid gastric contents must effect a considerable reduction in acidity just by neutralization alone. Likewise, the chloride concentration of the parietal secretion will undergo diminution, but this is solely a consequence of the dilution effect.

Since the rate of salivary secretion and its composition are both highly variable, it is easier to prevent admixture of saliva with the stomach contents than to devise an arithmetical correction, such as was described above for dilution by the test-meal. In fact, in clinical practice at the present time, it is usual to ask the patient not to swallow any saliva, once the tube has been passed, but to expectorate it throughout the analysis. For purposes of quantitative investigation, such a procedure is unreliable because there is bound to be some drainage into the stomach in spite of the patient's cooperation, and without this cooperation the drainage may be considerable. As for a more reliable technique for use with human subjects over a period of several hours, none such is at present available. For these reasons, it is impossible to attempt any quanti-

tative evaluation of the effect of salivary admixture on gastric acidity until such time as a suitable procedure may be devised for the purpose. In view of this, we are attempting at the present time to develop a technique for completely eliminating this undesirable contaminant from all such physiological investigations on humans, and we shall report on it as soon as progress of the work warrants.

REGURGITATED DUODENAL CONTENTS

Of all the mechanisms which have been suggested to explain the ordinary reductions in gastric acidity, the one proposed by Boldyreff (1915) has been more widely acclaimed than any other. This hypothesis states that whenever the acidity of the stomach contents is greater than about 0.15% (40mN), on passing into the duodenum this gastric fluid stimulates the flow of the several intestinal secretions and also induces a regurgitation of the duodenal contents into the stomach. Since the admixture of pancreatic secretion, bile, and succus entericus contains a considerable concentration of buffer salts, especially bicarbonate and some phosphate, such regurgitation must result in a marked reduction in acidity of the gastric contents—particularly that portion of gastric fluid which happens to be present in the antral region at the time of regurgitation. When the stomach contents, thus partially neutralized, passes into the duodenum, it no longer evokes a reflux of intestinal fluid and regurgitation is consequently interrupted until a fresh portion of more highly acid stomach contents is again passed through the pylorus—whereupon the entire process repeats itself. In short, we are confronted with an automatic process of acidity regulation, based on the inability of the duodenum to tolerate a fluid that is more acid than 0.1-0.15% HCl.

This theory has been supported by many outstanding investigators—among them Spencer, *et al* (1915); Bolton and Goodhart (1922); Hicks and Vischer (1915); Elman *et al* (1934); and more recently Wilhelmj, Neigus and Hill (1934)—although their evidence is far from conclusive. With an increase in our knowledge of the acid-base composition of the several intestinal secretions, the major responsibility for this neutralizing action came to be placed on the pancreatic secretion as over against the bile, because of the considerably higher bicarbonate concentration in the former than in the latter. Thus, Gamble and McIver (1928,b) reported the bicarbonate concentration of dogs' pancreatic juice as 79mM (the phosphate concentration was 1mM), whereas in hepatic bile from the same animal, the bicarbonate concentration was 34mM (Reinhold and Wilson, 1934). Even in human gall bladder bile the value is low; Reinhold, Ferguson and Hunsberger (1937) give a mean value of 19mM for 13 individuals without obvious bladder pathology. Of course, it may be questioned whether bicarbonate alone is responsible for this neutralizing action; perhaps the protein or other buffer salts may also play a role here, in which case the bile may be no less important than the pancreatic secretion. Further discussion of this point must be left for another occasion, but certainly the question of relative neutralizing efficiencies of the several duodenal secretions should be investigated more meticulously in terms of buffer capacity measurements.

On the other hand, it has been pointed out by Shay, Katz and Schloss (1932) that most of the support for

this theory about duodenal regurgitation is a matter of opinion rather than of observation. Thus, we find an equally imposing list of investigators (e.g., Baird, Campbell and Hearn, 1924; Yesko, 1928; McCann, 1929) aligned in opposition to Boldyreff's idea concerning the regulation of acidity within the stomach. Most of this contrary evidence, however, is based on results obtained following surgical manipulation of the stomach and duodenum. Shay and his coworkers, on the contrary, have employed a straightforward physiological technique, in humans, based on the excretion of bromsulphalein in the bile and its quantitative determination in the several specimens of a fractional gastric analysis, in which tap water, dilute HCl, or other agent was used as a test-meal. As a consequence of their well-planned and thorough study, these authors concluded that duodenal regurgitation "can and frequently does take place," but it is neither important nor regular enough to be a major factor in normal control of gastric acidity.

Furthermore, it is a well known fact that the secretory curve of an isolated fundus pouch in a dog usually manifests the same sort of deviations from maximum (parietal) acidity that are found in fractional curves from humans. For several illustrative acidity-time curves of the former variety, see Figs. 2a and 2b of the paper of Hollander and Cowgill (1931), which were obtained both with food and with histamine as stimuli. In all cases, the curves start at a very low acidity, rise to a considerable height above this value, and then fall off again; sometimes they manifest intermediate fluctuations of considerable magnitude as well. Since such a gastric pouch is completely separated from the main course of the digestive tract, it is obvious that regurgitation of duodenal contents cannot possibly be a factor in this situation. Nevertheless, we find evidence here of all the fluctuations in acidity which we observe ordinarily in the intact stomach of dog or man. Hence we may conclude that the mixture of intestinal secretions is not the sole agent of acidity reduction within the gastric cavity—nor, perhaps, even an important one. Actual evaluation of its importance in the mélange of influences must await more extensive and quantitative investigation. Whether or not the duodenal fluids are effective agents of acidity reduction in the stomach, there can be no doubt that once the gastric fluid has entered the small intestine it does come under the influence of these buffer-containing secretions—but this situation is of no concern to us at the present time.

VARIATIONS INHERENT IN THE Parietal SECRETION ITSELF

All three of the foregoing agents of acidity reduction are extra-gastric in respect to their origins. From the preceding paragraph, however, it is apparent that acidity variations of considerable magnitude may be observed under conditions such that none of these agents can possibly play a role; i.e., in gastric pouches isolated from the digestive tract proper. Consequently, we next turn our attention to the several mechanisms of distinctly intragastric origin which may be responsible for the normal lowering in acid concentration.

The first of these is inherent in the widely known theory of Rosemann (1907) which maintains that the acidity of the parietal secretion is not constant but that it undergoes variations in magnitude parallel with the variations in rate of formation of the secretion.

This view, of course, is diametrically opposed to Pavlov's earlier belief in the matter—namely, that the secretion is poured out by its parent cells at an acidity level which is relatively invariant. Rosemann based his argument on the following: (1) Direct and universal observation of variation in acidity in the course of any single experiment with dogs, the variations being unmistakably correlated with the rate of secretion. (2) A belief that variations in acidity may occur even in the absence of mucus, the agent which Pavlov held to be chiefly responsible in this respect. (3) In general the concentration of total chloride (both acid and neutral chloride) varies but slightly, an observation which is demanded by Rosemann's hypothesis and is consistent with his entire view of the process of formation of the gastric HCl.

In the course of an extensive review of these opposing theories of Pavlov and Rosemann (Hollander, 1934), each of these specific arguments was analyzed and refuted in turn. Thus, it can be shown that the rate of secretion and the acidity in dogs are not always parallel with each other, and that the chloride concentration is not constant, but decreases as the acidity diminishes, though at a much slower rate. Also, it was possible to demonstrate by direct experimental evidence that Pavlov's contention is the correct one; i.e., that if the proper experimental conditions be maintained, acidity values may be relatively constant over a long period of time and independent of the individual animal or the type of stimulus employed (food or histamine). True, the acidity of the parietal secretion varies with changes in osmotic pressure of the general circulation—according to the views which are more recent than those of Rosemann (Gilman and Cowgill, 1933; Hollander, (1934,b)—but these osmotic changes, by their very nature, must be small compared with those which occur in the fluid of the gastric cavity. Hence, it may be concluded that at least this particular mechanism cannot be held accountable for acidity regulation either in the dog or, most likely, in the human.

ABSORPTION OF HYDROCHLORIC ACID BY THE GASTRIC MUCOSA

The notion that the concentration of HCl within the intact stomach or the stomach pouch may be reduced by a physical process of absorption is one which as yet has not acquired many adherents. Without offering any experimental evidence to support their contention, Shay, Katz and Schloss (1932) conclude that "with the introduction of acids into the stomach (of humans), some very rapid mechanism is brought into play. This mechanism, being neither one of neutralization nor of dilution, we believe is very likely one of absorption." According to this view the HCl would be taken into the gastric mucosa—presumably along with water molecules—and passed on to the tissue fluid and hence into the general circulation.

A modified version of this mechanism has been advanced by Teorell (1933). This investigator believes that, as HCl diffuses out of the stomach, through the mucosal wall, neutral chloride (e.g., NaCl) passes into the gastric cavity. More technically, there exists normally across the gastric mucosa an exchange of H-ion from the gastric juice and Na-ion from the tissue fluid or blood. Although Teorell did not demonstrate directly that such an ionic interchange occurs

in the mammalian stomach, he did perform numerous physico-chemical experiments of an analogous nature. In these experiments, solutions of HCl and NaCl were separated by non-vital membranes, and the changes in H-ion and Cl-ion concentrations which he obtained were quantitatively similar to those which were observed, for instance, on placing mixtures of HCl and NaCl in a cat's stomach in an acute experiment.

Although these views are certainly worthy of consideration and even of experimental examination, yet, so far as I know, they have received very little of either. Nevertheless, there are several considerations which throw considerable doubt on the likelihood that any such process of absorption, with or without ionic interchange, actually occurs. For one, a process of this kind can in no way account for the low acid values at the beginning of secretion, although it may explain the post maximal drop in acidity. For another, certain observations of my own, I believe, contribute evidence in disproof of both of these absorption mechanisms. This evidence is based on an extensive series of experiments on the acidity of gastric juice which has been formed in dogs' fundus pouches and kept there by means of a sphincter action on the mouth of the pouch. Under such conditions, it was found that gastric secretion could be retained in the pouch for considerable periods of time without giving any indication of having suffered a significant diminution in its acidity. Observations of this kind were made with juice of acidity values as high as 150mN, and for time intervals as great as 9 hours. Occasionally, fluid collected from such a pouch did possess an acidity considerably lower than the maximum for pure parietal secretion, but this reduction was shown to be the result of dilution and neutralization by non-acid fluid which was present within the pouch before secretion started. When this contaminant was washed out, by discarding the first portion of juice secreted, the acidity of the subsequent portions remained quite invariant, thus supplying positive evidence in refutation of acidity reduction by absorption. Of course, it might be argued that the absorption occurs through some part of the gastric mucosa other than that included in the fundus pouch. The validity of this objection cannot be questioned, though I doubt its probability; in any case, now that the hypothesis has been advanced in the gastric literature, it must be given full consideration and investigated from various aspects.

EVIDENCE FAVORING SECRETION OF A BUFFER CONTAINING FLUID

Before going on to consider the remaining factors which may play a role in acidity reduction, let us stop to examine a considerable body of evidence which, I believe, proves well-nigh conclusively that reduction in acidity is associated with the presence of substances which are not contained in the parietal secretion itself. Some of this evidence is derived from my own investigations; the bulk of it is cited from the work of others. The facts are as follows:

(1) When gastric juice from fundus pouches was analyzed (Hollander, 1934,b) for various chemical constituents—i.e., neutral chloride, combined acidity, total solids, ash, and phosphate—it was found that all of these substances are present in specimens of lower acidity and in concentrations of significant magnitude. With rise in acidity of the specimen, however, the concentration of each of these constituents diminished

(Table I) until, in the specimen of highest acidity investigated (158mN), combined acidity and total phosphorus were entirely absent, neutral chloride was down to 5mN, and total solids had dropped to 0.12%—of which organic solids comprised 0.04% and inorganic solids the remainder. These decreases were all progressive throughout the range of acidity studied. It follows, therefore, that there is a definite negative correlation between the acidity of gastric juice and its

TABLE I

Variation in concentrations of various chemical constituents of dogs' gastric juice with acidity (from Hollander, 1934,b)

Specimen Number	1	2	3	4	5
Total acidity, mN	111	135	144	155	158
Free acidity, mN	107	133	141	153	156
Combined acidity, mN	4	3	3	2	2
Neutral chloride, mN	25	22	18	7	5
Organic phosphorus, mN	—	—	—	0	0
Inorganic phosphorus, mN	—	—	—	0	0
Total solids, %	0.35	0.24	0.20	0.13	0.12
Ash as chloride, %	0.20	0.17	0.12	0.09	0.03
Organic solids, %	0.15	0.05	0.05	0.04	0.04

content of the several chemical factors enumerated, a correlation which can be explained best, if not solely, by the addition to the parietal secretion of varying proportions of a non-acid fluid which contains alkali salts, protein, phosphate, etc.

(2) Similar observations on human gastric juice have been reported by Helmer (1934), with histamine as the stimulus. This investigator studied total base (equivalent to neutral chloride), nitrogen, phosphorus, and mucous sugar, in a series of specimens of different acidities, and found that the concentrations of all four of these chemical constituents increased as the acidity diminished. Webster (1930) found the same to be true for neutral chloride and protein, the latter determined by precipitation and weighing. Likewise, Pollard, Roberts and Bloomfield (1928) observed that changes in nitrogen and total base concentrations are parallel in histamine secretion from human subjects, and that the values for both increase as the total acidity falls off. Dienst (1931) determined the total nitrogen concentration in 86 samples of human gastric juice, free of saliva and bile, and obtained results which are wholly in accord with these others.

(3) In order to determine the nature of the buffer substances which are present in gastric secretion and which manifest themselves on titration as "combined acidity," Mitchell (1931) studied the effect of titration, dialysis, and aeration on fasting contents from human stomach. He also studied pilocarpine and histamine juice from the stomachs of dogs. As one might expect, he found considerable amounts of protein and protein degradation products, with some phosphate in small amount. In non-acid secretion (i.e., fluid with an acid deficit, like the pyloric secretion) by far the greater part of the buffering power was found associated with

alkaline bicarbonates. His evidence for these statements appears to be incontrovertible.

With this array of facts before us there can be little doubt that the usual lowering of gastric acidity is quantitatively correlated with the concentrations of a number of substances which, by their very chemical natures, must be causative agents in this lowering. Furthermore, this correlation obtains, not only for the intact stomach of man and dog, but for isolated stomach pouches in the latter animal as well. Thus, our problem would seem to narrow down to a search for one or more non-acid, buffer-containing fluids which are elaborated by the gastric mucosa itself. The action of such a fluid would be two-fold: one of neutralization and the other of dilution; which of these is more important will depend on the nature and concentration of these buffer substances. Let us therefore proceed to consider the various secretions which may possibly function in this respect.

PEPSIN SECRETION

The first of these fluids to be considered is the enzyme-containing secretion of the peptic or body chief cells. About the composition of this fluid we know practically nothing at the present time except that it contains the pepsin and probably also the rennin. Nor can we say anything about its volume relative to that of the parietal secretion, nor about its content of salt or buffer substances. It seems fairly likely, however, that the volume-rate of secretion of this fluid is extremely small, even when compared with the volume of mucus secretion. This might explain why studies on the correlation of acidity and pepsin activity are manifestly inconsistent. Clinical studies like those of Hirsch-Mammoth and Rindfleisch (1925), and Butcher (1926) frequently indicate a parallelism of the acidity and pepsin curves for any one subject. On the other hand, it has been pointed out by Gilman and Cowgill (1931) that in general "the highest proteolytic power of dog's histamine juice was associated with low acidities, (and) conversely high acidities may be associated with very low pepsin." In keeping with this finding these workers observed "a parallelism between pepsin and neutral chloride concentration in the gastric juice." The best investigation of the correlation of acidity and pepsin in humans is the statistical study of Vanzant, Osterberg, Alvarez and Rivers (1933) on 85 normal persons and 274 patients with duodenal ulcer. Following an Ewald test-meal the correlation coefficients of pepsin activity and free HCl were 0.51 and 0.65 for these two groups respectively; for gastric juice obtained after histamine stimulation, the ulcer group showed a correlation coefficient of 0.60. With values so low it is altogether impossible to assert the existence of any sort of well-defined statistical correlation between the two variables, but since the coefficients are in all cases positive it is probable that the general tendency is in the direction of increasing enzyme activity with increasing acidity. So, it may be assumed that if the peptic secretion plays any part in acidity reduction, its role is an extremely minor one and may therefore be dismissed for the time being.

THE DILUTION SECRETION

Even well before the end of the last century, it was reported that, when hypertonic solutions of HCl, NaCl, or glucose are introduced into the intact stomachs of humans or dogs, or into stomach pouches of the latter,

such solutions undergo a progressive decrease in concentration. (Roth and Strauss, 1899; Smith, 1884, and Von Mering, 1893). The processes suggested to account for this decrease in concentration were threefold: (1) osmotic diffusion, (2) secretion of HCl and pepsin-containing fluids, and (3) secretion of a specific "Verdünnungs Sekretion" or dilution secretion. Particular emphasis was placed on the last of these, although no direct evidence was adduced in support of its occurrence, nor was any suggestion made as to its possible chemical composition. Subsequent workers went so far as to suggest that this unknown secretion might be a solution of neutral chloride, with or without some source of alkalinity or buffer substance (see, for instance, Liu, Yuan and Lim, 1934; also Engstrom, 1935); various other names, such as "Nebensekret" and "accessory" secretion were proposed for this fluid.

Actual evidence regarding its chemical make-up was not forthcoming until the present decade, when Webster and Komarov (1932) reported that gastric juice from various sources contains soluble muco-protein, which is distinct from the mucus of the surface epithelium and which, they believed, is secreted directly by one of the gastric gland cells. In the same year, I pointed out (Hollander, 1932) that the quantitative relation which exists between the concentrations of neutral chloride and of acid in dogs' fundus pouch juice could be explained very satisfactorily by the presence of an "alkaline constituent" of the gastric juice, the acid-base composition of which is similar to that of blood plasma; i.e., an isotonic solution of alkali and alkaline earth chloride, bicarbonate, phosphate and proteinate, with the neutral chloride concentration in the neighborhood of 100mN. This "alkaline constituent" might conceivably be a mixture of mucus, peptic secretion, epithelial detritus and possibly a secretion corresponding to the "dilution secretion" of Roth and Strauss. This hypothesis was subsequently supported by some evidence of Wilhelmj and his coworkers on the neutral chloride concentration of the non-acid secretions of the stomach (Wilhelmj, Neigus and Hill, 1934; Wilhelmj, Henrich and Hill, 1934). However, these investigators believe that the non-acid constituents of the gastric juice play only a secondary role in acidity regulation, and that duodenal regurgitation is of far greater consequence in this process.

Viewed from its histological aspect, also, the concept of a specific "dilution secretion" is entirely tenable. In addition to the mucous cells of the surface epithelium there are three other kinds of cells in the gastric tubules: the peptic cells, the parietal cells and the mucoid cells (also called the neck chief cells, Zwischenzellen and Nebenzellen). The function of the latter is quite unknown, but Babkin (1931) has suggested that they may be the source of the soluble muco-protein of gastric juice and hence of this dilution secretion.

It appears, from the foregoing, that there is already considerable evidence in favor of the existence of a specific non-acid gastric secretion which plays a role in acidity regulation. It is essential now that direct experimental efforts be made to establish the existence of such a fluid and to determine its various chemical characteristics.

THE MUCOUS SECRETION

We have already considered two possible sources of buffer-containing secretion from the gastric mucosa.

The third (and remaining) possibility is mucus, the viscous secretion which is elaborated by the surface epithelium. It has long and universally been recognized that, thanks to its high viscosity and adhesiveness, this fluid exercises a protective function against mechanical abrasions of the inner gastric wall. That it may also act chemically to neutralize the HCl is an idea that can be traced back to the early days in Pavlov's laboratory (Pavlov, 1910). These workers made no attempt to elucidate the chemical processes involved, but they undoubtedly credited the mucus with a major part of the acid-neutralization which occurs within the stomach. This view has found many champions during the intervening years, but it has also encountered considerable resistance. Much of this opposition has come from Rosemann and his supporters, the views of whom we have already discussed. Before analyzing the arguments which have been advanced against the acid-neutralizing role of mucus, let us consider what is known today about the chemical properties of this secretion.

In the first place, we must differentiate between *mucus* and *mucin*. The latter is a solid, a distinct chemical substance of the class of conjugated proteins, and it forms one of the constituents of the mucous secretion proper. The native secretion from the surface epithelium, on the other hand, is a homogeneous fluid, highly viscous, tenacious, transparent (its frequent opalescence is probably due to epithelial detritus) and odorless. Different investigators have collected it from whole stomachs, fundus pouches, or pyloric pouches. The assumption that the secretion from the pyloric antrum is practically identical with the HCl-free fluid from the fundus is generally accepted at the present time, although it is recognized that the relative amount of pepsin secretion which is mixed with the mucus may differ in the products obtained from the several sources.

Let us next compare the essential chemical properties of the gastric mucus as reported by these various investigators. As is evident from Table II, some of the earlier workers observed that its reaction to litmus was neutral or even distinctly acid—which corresponds to a pH value of no greater than 7.0 and possibly even less than 6.0. However, as early as 1901, Schemiakine (in Pavlov's laboratory) found that the pyloric secretion from the dog may be distinctly alkaline. Subsequently, it was pointed out that an alkaline reaction to litmus is far more common than an acid one; in fact, a pH appreciably greater than 7.0 may be obtained consistently if the following precautions be taken: (1) In the preparation of the pyloric pouches, it is essential that the fundus mucosa (i.e., that containing the parietal cells) be completely excluded; and (2) in the collection of mucus from fundic pouches, it is essential that the acid-forming cells be in the resting state, even if it be necessary to inject atropine for their inactivation. Thus, it is not surprising that Gamble and McIver (1928,a) were able to attain a pH value as high as 8.4. In some of the recent work in this laboratory we have reached values above 9.0—as indicated by a distinct pink coloration to phenolphthalein. Although we have observed this high value repeatedly, the conditions essential for obtaining such a markedly alkaline fluid have not yet been worked out

3. It is important to remember that a solution may be distinctly acid to litmus and yet possess a pH value which differs from neutrality by no more than 1 pH unit, i.e., no less than 6.0.

completely, and we are engaged at present in attempting to learn more about its source and significance.

So much for our present knowledge concerning the pH of the mucus secretion; let us now digress to consider why the pH is wholly inadequate as a measure of titratable alkalinity or acidity. Physical chemists generally admit that, of two solutions possessing different values, that having the lower pH (i.e., the more acid) may actually possess a greater neutralizing power for free HCl than the solution of higher pH value, although this is not necessarily so. One condition requisite for this anomalous situation is this—that the more acid solution possess a higher concentration, in terms of normality, than the more alkaline one. Such a difference in neutralizing power corresponds to a difference in buffer capacity, a concept which is applicable to acids and alkalies as well as to buffer salts. By way of illustrating this principle, let us compare a 0.01 N solution of NaOH with a 0.1 N solution of NH_4OH . The pH of the NaOH is 12.12,

going discussion has one very important and practical implication: since we are interested in the acid-neutralizing power of the mucous secretion, it is essential above all else that we know its titratable alkalinity. The pH value is important on other scores, but it tells us nothing about the ability of the mucus to neutralize the HCl of the parietal fluid. Reference to Table II, column 5, reveals only three references to the titratable alkalinity. Gamble and McIver (1928,a) reported a value of 11 mN for the alkalinity of the pyloric secretion of the cat, and Bolton and Goodhart (1931) found values of 30-44 mN for the non-acid fluid from the whole stomach of the same animal. For the dog, the only such data on record—so far as I have been able to find—are those of Schemiakine (1904) who reported titration values in terms of Na_2CO_3 which vary from 0.026 to 0.081% (average: 0.048%). These numbers correspond to 5-15 mN (average 10 mN) respectively. It is evident from these values that the fluids studied possess the ability to neutralize gastric acidity to some degree, and it is possible that the pure

whereas for the NH_4OH it is 11.27 and therefore more acid by almost a whole pH unit; yet, volume for volume, the NH_4OH will neutralize 10 times as much HCl as will the NaOH. The anomaly becomes even more marked if we compare 0.01 N NaOH with an $\text{NH}_4\text{OH} - \text{NH}_4\text{Cl}$ buffer mixture in which the concentrations are 0.1 N and 0.8 N respectively. In this case the presence of the NH_4Cl actually decreases the pH of the NH_4OH to 8.4; this is 2.9 pH units less alkaline than the 0.01 N NaOH. Nevertheless, the ability of the $\text{NH}_4\text{OH} - \text{NH}_4\text{Cl}$ buffer mixture to neutralize HCl remains practically identical with that of the salt-free NH_4OH and 10 times that of the NaOH of considerably higher pH value¹.

To the uninitiated, this distinction between pH and titratable alkalinity or neutralizing power is undoubtedly confusing, yet it can be justified on both theoretical and empirical grounds. An explanation of the whys and wherefores of this differentiation is so technical and so involved as to be quite impossible at this time. For our present purposes, however, the fore-

mucus secretion, were we able to collect if free of all contaminants, might be found to possess an even higher value for the titratable alkalinity. In view of the scarcity of evidence on this score, it is apparent that a considerable amount of investigation of this most important property remains to be done. Such a study must be systematic and should attempt to correlate the variations in alkalinity with the concentrations of the several other constituents of the secretion.

Concerning the other chemical characteristics of mucous secretion, there is nothing that can be said with any assurance. For the total base content (i.e., the metallic ions Na, K, Ca, and Mg), only one value has so far been reported; Gamble and McIver found 169 mN in a single specimen composed of a number of separate collections. This value suggests that the mucus secretion may be isotonic with mammalian blood, just like the parietal secretion, but in order to justify this important generalization it is necessary that their finding be confirmed by independent investigation. Also it must be shown that the total base value remains practically invariant under a variety of phy-

1. The pH-concentration data for the foregoing calculations were taken from Michaelis (1926).

siological conditions, except such as likewise induce a change in the osmotic pressure of the blood itself.

In the case of the total chloride concentration, no such constancy has been reported, although 8 of the investigators have reported values for this constituent. In those investigations where at least several determinations of chloride concentration have been made, a considerable range of variation is noticeable; the greatest such variation is that observed by Ivy and Oyama (1921) who reported a range from 129 mN to 180 mN. It is noteworthy that no other investigator has reported a value as high as 180 mN, but that Bolton and Goodhart (1931) obtained values as low as 80 mN. What significance attaches to this high variability in chloride values it is impossible to say at this time. It may be that the variability is inherent in the very nature of the secretion, in which case it is important to discover what are the physiological factors which determine the chloride content of any one specimen. On the other hand, the total chloride concentration may be relatively constant, as in the case of the parietal secretion, and the observed variations may result from the admixture of other fluids like the pepsin and mucoid secretions. If this be the case a way must be found for collecting the mucus secretion more or less free of these contaminating secretions so that its properties may be studied in a state of relative purity.

For total solids and total ash (inorganic solids), the percentile values likewise show considerable variation. The highest value reported (Gamble and Melver, 1928,a) for total solids is 2.5%, which is high indeed. Since Ivy and Oyama reported a value which is practically identical it may be that this value is actually characteristic of the secretion itself, but this fact must be confirmed on a considerable series of specimens before we can accept it. Three out of four studies report the presence of pepsin; only Ivy and Oyama were able to obtain an enzyme-free product. In view of the presence of peptic cells throughout the entire fundus and in a considerable part of the pyloric antrum as well, it is not surprising that difficulty has been experienced in obtaining mucus which is pepsin-free. For a long time it was believed that the pyloric glands are pepsin-forming, a theory which can be traced back to Heidenhain, but thanks to the histological work of Bensley (see Ivy and Oyama, 1921) there is no longer any doubt concerning the error of this view. Values for specific gravity are also included in the table, but since this property is dependent on the content of total solids, it merits no further discussion at this time.

ARGUMENTS AGAINST MUCUS AS A MAJOR FACTOR IN ACIDITY REGULATION

From the foregoing discussion of the chemical characteristics of gastric mucus, it would appear that this secretion may well function as an agent of acidity reduction in the stomach. However, two specific arguments have been advanced in opposition to this possibility. These are (1) that the secretion is not sufficiently alkaline to be effective, and (2) that its volume-rate of secretion is so low as to be insignificant in the presence of any but the smallest quantities of parietal secretion. To these I should like to add a third possible objection; namely, that the chemical properties reported for mucus secretion may be due in great part to the presence of some other non-acid secretion. Let

us consider the validity of each of these objections in turn.

Concerning the question of inadequate alkalinity, we have already seen that pH values as high as 8.0-8.4 have been reported for dog and cat, though by no means consistently. Also, from our own unpublished observations, there is some reason to believe that the normal pH value in the latter animal may sometimes run as high as 9. Furthermore, I have already shown above that the "titratable alkalinity" is a far more significant criterion of neutralizing power than the pH, and titration values as high as 44 mN have actually been observed in the case of the cat. It must be admitted that no one has yet attempted a systematic investigation of the titratable alkalinity, but there can be no doubt, even at this early time, that the value is sufficiently high to permit of an appreciable degree of acid-neutralizing power.

The second objection, that concerning the inadequate volume of mucus secreted, is a more serious matter. Judging by the volume of precipitated mucin present in the average sample of gastric juice from an experimental pouch dog, the volume of mucus, relative to that of the parietal secretion, is small indeed. But, so far as I know, there is no published evidence to indicate that the volume of mucin precipitated from a sample of gastric mucus is even approximately the same as the volume of native secretion from which it was derived. Again, it has been pointed out that the volume of mucus secretion obtained from a fundus or whole stomach pouch by gentle massage of the mucosa is invariably small, and nobody has yet been able to devise a method for increasing it appreciably. Chemical irritants like AgNO_3 and mustard oil do yield a larger volume, but the fluid is in the nature of an inflammatory exudate rather than a true secretion (Bolton and Goodhart, 1931). Consequently, until we are in possession of more extensive evidence on the normal physiological stimulus to mucus flow we are forced to admit the utter inadequacy of this alkaline secretion as a major factor in the process of acidity regulation.

Likewise with the question of purity of the material which has been called mucus secretion by the various investigators who have worked with it. Sometimes the acid-free product from the gastric mucosa is as viscous as a partially dried mucilage, whereas on other occasions it behaves like a fluid of merely moderate viscosity. Does this variability in viscosity betoken merely a change in physical characteristics which results from differences in physiological conditions of formation and secretion, or does it betoken the presence of some other, highly fluid, acid-free, secretion mixed with mucus of extremely high viscosity and adhesiveness? Certainly, in the absence of specific evidence to the contrary, we must admit the possibility that much of what is being called mucus is actually a mixture of this secretion with the mucoid or dilution secretion which has already been discussed above. One might expect a fair degree of constancy in the chemical properties of so specific a secretion as mucus, and the high variability in the analyses reported is further evidence of the presence of at least two secretions from different cellular sources in this fluid which has been accepted for analytical purposes as pure mucus.

Granted the actuality of such contamination, we are then confronted with these possibilities: either (1) the neutralizing power of pure mucus secretion is even higher than that indicated by the observations of

Table II (2) or else, it is considerably lower and the bulk of the titratable alkalinity reported by Schemiakine, Gamble and Melver, and Bolton and Goodhart is contributed by the diluting secretion. For the time being, therefore, we must rest content with the knowledge that mucus from the surface epithelium may be an important factor in the process of intra-gastric acidity regulation. By the same token, however, its influence in this regard may be wholly negligible and its chief function in the gastric cavity may be that of a mucosal lubricant against mechanical and chemical irritations. And so again we are confronted with a lack of factual information which must be remedied before we can possibly formulate any precise ideas along these lines.

CONCLUSION

The foregoing discussion attempts to present all the factors in the course of a gastric analysis which co-operate in lowering the normal gastric acidity from its initial high value of the parietal secretion. One of these—admixture of test meal with stomach contents—is extraneous and non-physiological, and a method has been described whereby in future investigation its influence can be corrected for quantitatively. A second of these factors—variations in composition of the parietal secretion itself—finds little support today by reason of the evidence which has already been accumulated against it. The six remaining factors—admixture of saliva, regurgitated intestinal contents, peptic secretion, a specific dilution secretion, mucous secretion, and reabsorption of HCl—are all possibilities which require painstaking investigation. Thus, this discussion is intended to serve as an analysis of the broad problem of acidity regulation, looking forward to a quantitative evaluation of these several factors. From the evidence presented, there can be little doubt that the observed variations in gastric

acidity are due primarily to neutralization by buffer substances—protein, phosphate, and bicarbonate—and to dilution by the fluids which contain them. But which are these fluids, and is there one which serves to a greater degree than any other in the capacity of buffer-containing secretion?

From one aspect this problem reduces to the question: What are the physiological factors which give to an acidity curve the particular shape it has? To this extent it is essentially academic in interest, even though fundamental. From another aspect, however, the problem deals with the mechanism by which the body normally reduces the acidity from a value in the interval 160-170 mN to one considerably lower and which the mucosa can tolerate without detriment to itself. Considered from this angle, the problem is a vital one for the clinical gastro-enterologist who is concerned with a procedure which he can utilize to reduce or eliminate free acidity wherever this may be indicated. With a complete understanding of all the factors involved in this acidity reduction process, it is hoped that we may eventually be able to avail ourselves of at least one of them as a physiological therapeutic measure in cases of gastric or duodenal ulcer. Such a practical application requires a knowledge, not only of the chemical processes involved in the action of this factor, but also an understanding of the stimulatory mechanism whereby this factor can be evoked. Thus, even for so utilitarian a purpose, we find ourselves under the primary necessity of unraveling these fundamental physiological phenomena—which means simply that the physiology of the gastro-intestinal tract is still a very young science and that much research remains to be done before it assumes as prominent a place in our text-books of physiology as is commensurate with its importance.

The Gastric Secretory Curve Before and After the Mann-Williamson Operation, and its Bearing on the Normal Regulation of Gastric Acidity

By

CHARLES M. WILHELMJ, M.D.

and

REX W. FINEGAN, M.D.*

OMAHA, NEBRASKA

IN previous publications (1, 2, 3) it was shown that there are two distinct and separate mechanisms normally responsible for the control of gastric acidity, namely *duodenal regurgitation* and *acid inhibition*. Duodenal regurgitation becomes most pronounced near the end of the gastric secretory curve and results in the entrance of non-acid duodenal secretions into the stomach. Acid inhibition becomes active when the acidity of the gastric contents reaches a certain threshold value and results in a decrease in the amount of acid secreted without a change in its concentration. The inhibiting action of the acid gastric contents is exerted by an effect in both the stomach and the intestine.

In the normal intact stomach these two mechanisms are in operation simultaneously and it is very difficult to determine the exact role played by each. In order to separate them, the gastric secretory curve was previously studied in whole stomach pouches and compared with the curve found in the intact normal stomach (1). Although the results of these studies were very definite, they were open to criticism, first because of the use of the whole stomach pouch preparation, and second because the comparisons were not based on the findings in the same animal before and after the operation. In order to meet these criticisms and to obtain further information regarding the exact role played by these two mechanisms, the problem has been reinvestigated using the Mann-Williamson operation in which the duodenal secretions are drained into the terminal ileum but in which the continuity of the gastro-intestinal tract is re-established.

METHODS

A two percent Liebig's extract test meal containing 15 mgs. of phenol red per liter was used in all studies. The methods and calculations employed have been described in previous publications (1, 4). From 7 to 10 satisfactory fractional gastric analyses were obtained on each animal before operation and, on most dogs, from 9 to 12 fractional analyses after operation. Samples were removed from the stomach every half hour for two hours or until the stomach emptied. The stomach was emptied as completely as possible when the last sample was removed. On each gastric sample the following analyses were made:—percent of phenol red, milligrams percent of total chloride and neutral chloride (and by difference the acid chloride), a Pettenkofer test, and the total titratable acid using Brom cresol purple as an indicator.

*Departments of Physiology and Experimental Surgery, Creighton University School of Medicine.
Submitted January 12, 1934.

The Mann-Williamson operation (Surgical Duodenal Drainage) was performed according to the original technique. The stomach was separated from the duodenum and the upper end of the duodenum was closed. An end to end anastomosis was made between the pyloric end of the stomach and the upper end of the jejunum. Great care was taken to avoid mechanical narrowing at the site of the anastomosis and when necessary the lumen of the jejunum was enlarged by an incision of the wall opposite the mesenteric attachment. The lower end of the duodenum was drained into the ileum by a small side to side anastomosis 6 to 8 centimeters above the ileo-caecal valve. The animals recovered promptly and studies were started on the 9th or 10th post-operative day and were usually continued until signs of ulcer appeared.

The usual kennel ration of dog biscuits, milk and karo syrup was given except on days preceeding an experiment when only milk and syrup was given.

Because of the delayed emptying time encountered after operation, the stomach was always carefully lavaged, before introducing the test meal, with three or four 300 cc. portions of the test meal to be used or until the lavage returned perfectly clear. This was done in order to remove any food or residual secretion present in the stomach.

RESULTS

Five dogs were studied both before and after operation and one dog only after operation. A total of 43 fractional analyses were performed before operation and 51 after operation.

I. The Average Secretory Curves Before and After Operation. (Figure 1 and Table I.

The average secretory curves after operation were decidedly different from those before operation. The differences involved chiefly the acid chloride concentration of the total secretions and the amount of non-acid secretion entering the stomach. Before operation the acid chloride concentration of the total secretions entering the stomach rose rapidly during the early part of the curve and usually reached its peak during the first or second half hour period; following this there was a decrease which was often very sharp and which continued until emptying of the stomach occurred. The amount of non-acid secretion entering the stomach before operation was relatively small during the first part of the curve but near the end there was an abrupt relative increase and accompanying this increase bile nearly always appeared in the gastric contents.

After operation the acid chloride concentration of the total secretions entering the stomach continued to

rise throughout the entire curve, the final drop being entirely absent, and the values reached were usually much higher than before operation. The amount of non-acid secretion entering the stomach was often nearly normal during the first and second half hour periods but instead of the normal abrupt increase before emptying occurred there was usually a decrease, so that the final samples frequently contained no non-acid secretions. Bile was absent from the gastric contents.

These striking differences in the average curves before and after operation are undoubtedly due to the fact that normally there is regurgitation of non-acid secretions from the duodenum, near the end of the curve, which by dilution and neutralization (5) lower the acidity of the *total secretions* entering the stomach. Regurgitation of duodenal secretions ordinarily does not occur after the Mann-Williamson operation.

II. Unusual Curves After Operation.

Out of a total of 51 experiments performed on five dogs after operation there were 9 in which the non-acid secretions increased near the end of the curve and in 6 this was accompanied by a decrease in the acid

chloride concentration of the secretions. These curves rather closely resembled the normal curves before operation. Five typical examples are shown in Table II. It appears quite certain that the non-acid secretion which entered the stomach in these experiments was intestinal contents which was forced from the jejunum into the stomach. The evidence for this statement rests upon the following facts: 1. In two such experiments fecal masses were found in the stomach before starting the experiment and in the gastric samples removed during the experiment. In a third experiment the gastric samples had a distinctly fecal odor. Except in these instances the gastric contents were very clean and practically odorless. 2. In two experiments the last gastric samples removed gave faint but unmistakably positive Pettenkofer reactions, thus indicating that some of the regurgitated intestinal material had come from the lower ileum. Matthews and Dragstedt (6) have shown that when the duodenum is anastomosed to the ileum as high as 40 cm. below the gastro-jejunoostomy there is often regurgitation of sufficient amounts of duodenal secretions into the jejunum to protect it from ulcer. This fact was also observed by Mann (7). It is therefore not

Results Before and After Operation on Dog 5. The acidity values were determined only by titration with brom-cresol purple, not by determination of the acid chloride. Asterisk marks samples in which there was marked water absorption from the gastric contents.

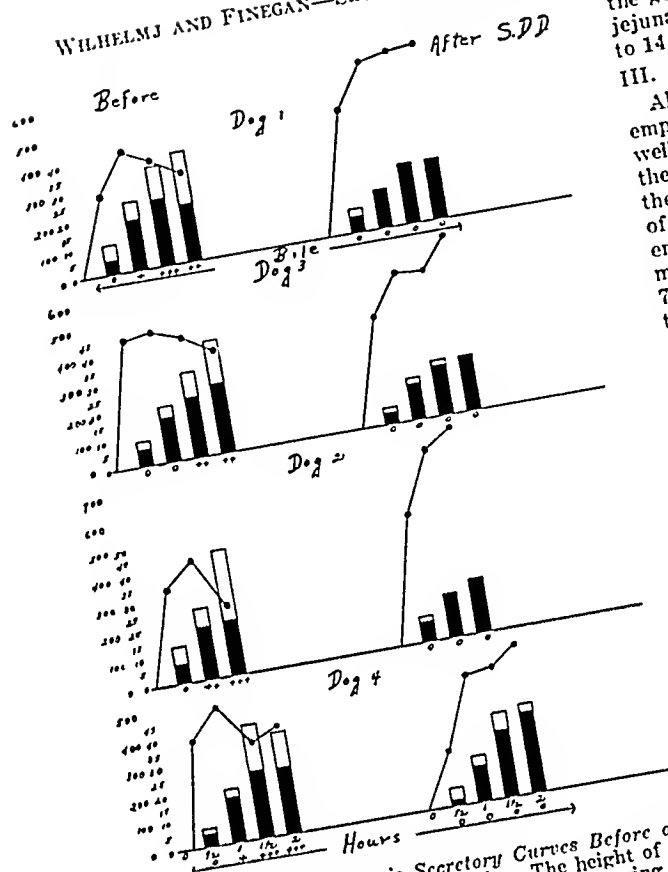

Fig. 1. Average Gastric Secretory Curves Before and After the Mann-Williamson Operation. The height of the rectangles shows the cc. of total secretions entering the stomach per 100 cc. of gastric contents. The black portion represents the cc. of acid secretion and the white portion the cc. of non-acid secretion. The line represents the milligrams of acid chloride per 100 cc. of secretion. The scale increasing by 5 indicates the milligrams of acid chloride per 100 cc. of secretion. + and zero signs refer to bile in the gastric contents as determined by the Pettenkofer reaction.

surprising that intestinal contents containing small amounts of bile could enter the stomach in two of our experiments. 3. In previously reported studies (8) the Mann-Williamson operation was performed but instead of anastomosing the duodenum into the terminal ileum it was drained into the jejunum by a large side to side stoma several inches below the gastro-jejunostomy. In such a preparation large amounts of bile and non-acid secretions were often found in the gastric contents, thus offering conclusive proof of the regurgitation of jejunal contents into the stomach.

These facts make it appear practically certain that the non-acid secretion was from intestinal contents in these unusual curves appearing in the stomach. It appears that this tendency is much more marked in some dogs than in others, since 5 out of the 9 experiments occurred in the same dog (dog 4), and this is seen to influence the average curve shown in Fig. 1. In some dogs curves of this type were never encountered. It is quite likely that regurgitation of intestinal and duodenal contents into the jejunum just below the gastro-jejunostomy, in some dogs, is one important factor responsible for

the great difference in the time of appearance of the jejunal ulcer after the Mann-Williamson operation (2 to 14 weeks) (9).

III. Gastric Emptying Time After Operation.

All animals showed a definite prolongation of the emptying time of the stomach after operation. This is well demonstrated in dog 5 (Table 1) by comparing the average volume of the last samples removed from the stomach before operation (33 cc.) with the volumes of the last samples after operation. This great difference existed in spite of the fact that the volume of test meal administered was reduced from 900 cc. before to 700 cc. after operation. This difference in emptying time was not caused by mechanical narrowing of the gastro-jejunostomy stoma, a fact verified at autopsy, but was quite likely the result of a spastic contraction of the jejunum which received the acid gastric contents. A similar prolongation of emptying time has been noted by other investigators (9, 10, 11) and Ivy (12) agrees that it is probably the result of jejunal spasm.

IV. The Acidity of the Gastric Contents Before and After Operation.*

In spite of the fact that the acidity of the total secretions entering the stomach was much higher after operation than before, the acidity of the gastric contents was practically unchanged or was slightly lower after operation. Two factors are responsible for this contradictory finding. First, in dogs 3 and 5 the emptying time of the stomach was so greatly prolonged after operation that in spite of a reduction in the amount of meal administered (900 cc. before—700 cc. after), the amount of meal remaining in the stomach to dilute the gastric secretions was much greater than before operation. The dilution of the gastric secretions by the test meal after operation was proportionately greater than the increase in the acidity of the secretions, hence the acidity of the gastric contents was slightly lower after operation than before. Second, in dogs 1, 2 and 4 it was possible to eliminate the factor of greater dilution of the gastric secretions by reducing the meal from 900 cc. before to 500 and 600 cc. after operation. This maintained about the same average amount of meal in the stomach before and after operation. This is shown by the average volumes of the last samples removed which were 35, 38 and 29 cc. before and 33, 48 and 72 cc. after operation. In spite of this, however, the average acidity of the gastric contents was almost the same before and after operation and it is obvious that some regulatory mechanism was in operation which controlled the acidity of the gastric contents. It appears quite certain that the regulatory mechanism responsible was that of acid inhibition. Previous studies have shown that as the acidity of the gastric contents rises the amount of acid secreted is progressively decreased. Acid inhibition thus appears to be an automatic mechanism controlling the acidity of the gastric contents independently of the acidity of the gastric secretions. Acid inhibition may also have been active in dogs 3 and 5 but because of the greater dilution of the gastric secretions by the test meal its role cannot be determined with certainty.

V. Absorption of Water From the Gastric Contents.

In previously reported studies on whole stomach pouches (1) in which the amount of non-acid secretion

*The acidity of the gastric contents is shown by the black portion of the rectangles in Fig. 1 and in column 2 of Table 1.

is small (13), we have shown that absorption of water from the gastric contents often occurs to such an extent that the amount of non-acid secretion may fall to zero while the apparent acidity of the pure acid secretion may rise considerably above the value determined by Hollander (14) (600 mgs. of acid chloride per 100 cc. or 0.170 normal acid). After the Mann-Williamson operation when no intestinal secretions regurgitated into the stomach similar changes were often found (Table I). In one experiment each on dogs 1, 2 and 5, water absorption became so marked that we observed a definite rise in the acidity of the gastric contents with an actual concentration of the per cent of phenol red to values ranging to 114 per cent of the value in the meal. Such observations can only be explained on the basis of absorption of water but not of acid from the gastric contents. Water absorption with concentration of the acid in the gastric contents may become so pronounced that the calculated amount of acid secretion may exceed the amount of total secretion. This is illustrated in Table I in the samples marked with an asterisk. It is quite likely that this process is going on to a variable extent at all times in normal dogs but is overshadowed by the regurgitation of relatively large amounts of non-acid secretions from the duodenum.

DISCUSSION

The above experiments show that the primary changes which occur in the gastric secretory curve after the Mann-Williamson operation are due to the fact that duodenal regurgitation is prevented. The curves of secretion after operation are almost identical with those previously found in whole stomach pouches

(1) and this similarity verifies a fact previously demonstrated (13), namely that the non-acid secretions of the stomach itself are too small in amount to cause any significant lowering of the acidity of the gastric secretions, unless the acid secretion is very small in amount.

Duodenal regurgitation and acid inhibition which are in operation simultaneously in the intact animal are dissociated after the Mann-Williamson operation and this separation has allowed us to determine the exact role played by each in the regulation of gastric acidity.

The present experiments justify the following statement regarding the role of these two mechanisms: The primary effect of duodenal regurgitation is to lower the acidity of the total secretions (gastric plus duodenal) entering the stomach; the acidity of the gastric contents may or may not be lowered depending upon the amount and acidity of the gastric contents in relation to the amount of secretions regurgitated from the duodenum. The acidity of the gastric contents is controlled primarily by the mechanism of acid inhibition. When acid inhibition occurs the acidity of the secretions is not influenced. Thus these two mechanisms are seen to play separate and distinct roles.

The above findings probably explain the results of Baird, Campbell and Hern (15) who found that the acidity of the gastric contents, after a gruel meal, was not changed by continuous aspiration of the duodenum which was stated to prevent regurgitation of duodenal contents into the stomach.

McCann (10) studied dogs before and after the Mann-Williamson operation and stated that there was no change in gastric acidity after operation. It is im-

Five experiments after the Mann-Williamson operation in which considerable amounts of non-acid secretions entered the stomach. The presence of fecal material or faintly positive Pettenkofer tests indicate that the non-acid secretions regurgitated from the intestine into the stomach.

portant to note that McCann studied the acidity of the gastric contents only, his methods not permitting him to study the acidity of the secretions.

Orndorff, Fauley and Ivy (9) also found only slight increases in the acidity of the gastric contents after operation. However, they noted that there was a marked continuous secretion and hypersecretion as evidenced by a high prolonged secretion continuing from 6 to 8 hours after a meat test meal. This is probably due to a prolonged intestinal phase since hypersecretion was not observed in our animals in which the experiments lasted only two hours and were therefore terminated before the onset of the intestinal phase. According to Ivy (12) this prolonged intestinal phase is not found in all dogs after operation.

Several of our dogs were studied through the phase of ulcer development, up to the time of perforation, but no changes were found in the gastric secretory curve which could be ascribed to the presence of the ulcer.

These studies are in agreement with those of McCann (10) in showing that the jejunal ulcer following the Mann-Williamson operation develops with an acidity of the gastric contents which is essentially normal.

Previous studies (8) have shown that if the jejunum is supplied with the secretions of the duodenum it will

apparently resist ulcer formation indefinitely. It would be interesting to know whether human cases of duodenal ulcer show changes in the gastric secretory curve which are similar to those found after the Mann-Williamson operation.

SUMMARY

1 Following the Mann-Williamson operation the acidity of the total secretions entering the stomach is much higher than before operation. During the gastric secretory curve the acidity of the secretions continues to rise and does not show the normal terminal decrease. The non-acid secretions entering the stomach are either very small in amount or absent. These changes are due to the absence of duodenal regurgitation.

2 The emptying time of the stomach is markedly increased after operation due apparently to jejunal spasm.

3 The acidity of the gastric contents shows little change after operation.

4 Evidence is presented which indicates that the acidity of the total secretions (gastric plus duodenal) entering the stomach is controlled primarily by duodenal regurgitation while the acidity of the gastric contents is controlled primarily by acid inhibition.

Review of Recent Practices in the Field of Gastro-Enterology at the University of Minnesota Hospitals

By

CHARLES E REA, M D *

THE development of gastro-enterology has been so rapid and complex in the past decade that a periodic review is helpful to glean the worthwhile from the outmoded practices. Accordingly the principles and practices in gastro-enterology at the University of Minnesota Hospitals are analyzed from the points of view of relating the diagnostic methods and forms of treatment that have proved most successful in our hands and of summarizing the different lines of research that are being carried on in this elude.

ULCER OF THE STOMACH AND DUODENUM

A Treatment by bile salts. During the past year Dr. Bergh of the Surgical Department has used bile salts (Bilron, Eli Lilly, gr V to X qid) in the therapy of benign gastric and duodenal ulcers with encouraging results. While our series of cases is small and the

mechanism of action is not understood, it appears that the administration of bile salts may prove to be a valuable adjunct in the therapy of ulcer.

B Acute perforation. Acute perforations of the gastro-intestinal tract rank high among the abdominal emergencies seen in this hospital. We have been interested in the factors influencing the development of peritonitis in these cases. In a general way the mortality from peritonitis following perforation of the gastro-intestinal tract depends on the number and virulence of the escaping organisms, which in turn depends on the size of the perforation, the length of time the perforation remains open, the number of organisms at the level of the perforation, the amount and fluidity of the material in the viscus at the time of perforation, the forces tending to carry the contents of the viscus out into the peritoneal cavity, etc. Al-

*Department of Surgery, University of Minnesota Medical School. Submitted January 27, 1937.

the general and local resistance of the host are important.

Drs. G. S. Bergh, W. F. Bowers and O. H. Wangensteen have established experimentally perforations at different levels of the gastro-intestinal tract of dogs. Most of the perforations consisted of unsutured linear incisions, one centimeter in length. The mortality following perforation of the empty stomach was 6.9%, but when the stomach contained food, the mortality rose to 86.7%. Injection of a sclerosing solution into the stomach wall before operation delayed closure of the opening and the mortality in fasting animals was increased to 40%. (Compare with mortality of perforating cancer of stomach in human cases). In the small intestine the mortality was 81.2% following duodenal perforations, 44.4% following jejunal perforations, and 100% following perforations of the terminal ileum. The mortality following perforations of the large bowel in dogs was 23.1%. The importance of having the gastro-intestinal tract empty or seeing that it is made empty as soon as the diagnosis of perforation is made is apparent from this study.

C. *Diagnosis and treatment of acute perforated peptic ulcer.* Our practice in cases of suspected perforated peptic ulcer is to immediately insert an indwelling duodenal catheter and apply suction. If the patient is dehydrated from vomiting or poor fluid intake, he is given intravenous saline solution. In cases of perforated ulcer seen at this clinic shock is not a prominent feature until the terminal stages.

After physical examination of the patient with a suspected perforated ulcer, X-ray plates are taken to determine the presence of free gas in the peritoneal cavity. Three films are taken: a flat (scout) film with the patient supine, an upright and a left lateral decubitus film (to visualize gas under the right lateral wall). If the stomach is full of gas, and no free gas is seen in any of the three plates, suction is again applied to the intlying catheter and the intragastric gases removed. One should not be satisfied that there is no free intraperitoneal gas present under the dome of the left diaphragm until this is done. The following experience has occurred in this clinic: a case of suspected perforated ulcer showed only a dilated stomach on fluoroscopic and X-ray examinations. However, on removing the gas from the stomach, free gas was demonstrated under the left diaphragm. Subsequent operation disclosed a perforated duodenal ulcer.

D. *"Forme fruste" type of ulcer perforation of the stomach.* Cases of suspected perforated ulcer with no free gas demonstrated in the peritoneal cavity have been regarded on occasion as the "forme fruste" type and have been treated conservatively (4 cases). The patients made an uneventful recovery. However, no hard or fast rules can be made in the treatment of such cases. Just how certain one is of the diagnosis from the history and physical findings decides whether the treatment is to be surgical or conservative in this "forme fruste" type.

The question arises as to how little gas is required to be visualized in the peritoneal cavity and what percentage of cases of perforated ulcer show pneumoperitoneum. Three out of four cases of perforated ulcer in this clinic show free gas in the peritoneal cavity. As little as 5 cc. of air injected under the diaphragm of human beings may be visualized by X-ray (Paine and Rigler).

E. *Bleeding peptic ulcer.* It is said that bleeding peptic ulcers never perforate. However, in this hospital three cases of bleeding peptic ulcer have perforated while the patients were under strict medical management.

In bleeding ulcers suction applied to an indwelling gastric tube is employed as part of the conservative treatment. By keeping the stomach empty, there is less chance of perforation due to distention of the stomach with blood; the bleeding has a better chance of being controlled as the stomach is contracted, and there is less danger of masked hemorrhage into the lower gastro-intestinal tract. Such suction has apparently not increased the bleeding in these cases.

THE GALL BLADDER

A. *Conservative treatment of certain types of gall bladder disease.*

In this clinic uncomplicated cases of acute cholecystitis are treated by means of bed rest, hot packs to the abdomen, sedatives, suction applied to an indwelling duodenal tube, and paroral fluids. About six to eight weeks after the acute symptoms have subsided, cholecystectomy is performed if X-ray studies show evidence of poor emptying of the gall bladder and stones. There have been no deaths in any of the cases treated in this manner.

Also cases of chronic cholecystitis with no roentgenologic evidence of stones in the gall bladder or clinical evidence of common duct obstruction are treated conservatively by means of bile salts and low fat diet. Dr. A. G. Rewbridge of this Department has presented indirect (X-ray) evidence that stones in the gall bladder may be dissolved by bile salts.

B. *Studies on the physiology of the gall bladder.* Dr. E. A. Boyden, Department of Anatomy, University of Minnesota, and co-workers have made some interesting observations on the physiology of the gall bladder. Boyden and T. M. Berman found that in a study of 33 ulcer patients, the rate of evacuation of the gall bladder was markedly increased. This was considered to be due to the increased acidity or motility of the stomach in these patients. Also, Boyden and W. P. Ritchie found that the emptying time of the gall bladder in patients after gastric resection was normal. Dr. Maude Gerdes and Boyden found that in pregnant women the emptying time of the gall bladder is longer than normal which is probably an etiologic factor in the production of cholelithiasis in pregnant women.

Drs. J. A. Layne and Bergh have investigated the effect of distention on the common bile duct of unanesthetized patients. They find that distention of the common duct by water introduced through a T-tube (previously inserted at time of exploration for common duct stone) causes pain in the epigastrium or right hypochondrium in all cases; this pain is referred to the interscapular and right subscapular region in 50% of the cases. Apparently the same effect is obtained from spasm, presumably at the sphincter choledochus.

C. *Cholangiograms.* In all suspected cases of common duct stone, cholangiograms are made routinely at the time of operation. The cystic duct is isolated and clamped, and then into the common duct a No. 22 needle is inserted and 5-10 cc. of diodrast is injected. General anesthesia is used; drop ether or nitrous oxide is given while the X-ray pictures are taken. While the film is being developed, the diseased gall bladder is re-

moved. If the cholangiogram is negative, the results of manual palpation of the common duct as well as the clinical history determine whether the common duct is to be explored.

D. *Differentiation between obstructions of the common duct due to malignancy and stones.* In patients with obstructive jaundice, to differentiate between obstructions of the common duct due to cancer and malignancy the quantitative determination of the amount of urobilinogen in the feces has proven most helpful. Dr. C. J. Watson of the Medical Department has found that normally one excretes up to 200 mg. of urobilinogen in the feces daily, and none or only traces in the urine. In a series of obstruction of the common duct due to carcinoma, usually in the head of the pancreas, he found that the obstruction tends to be complete in that there is no urobilinogen in the stool. In his experience, the obstruction has rarely proven to be complete over a four-day period in cases of common duct stone. In this clinic this test has proven to be the single most valuable aid to date in differentiating between obstructions of the common duct due to malignancy and stone.

SMALL INTESTINE

A. *Diagnosis and treatment of intestinal obstruction.* In 1931, Wangensteen was first to treat a case of acute mechanical intestinal obstruction conservatively by means of continuous suction transmitted through an indwelling duodenal tube. Since then his ideas regarding intestinal obstruction have been widely recognized. A book has been written dealing with the recognition and treatment of intestinal obstruction as practiced at this clinic; hence the different phases of ileus will be presented only briefly in this paper.

The symptoms of intestinal obstruction are intermittent, crampy, colicky pain, nausea and vomiting. Physically, the patient may be markedly dehydrated from vomiting. The abdomen is distended; visible peristalsis may be seen. If the obstruction is of long standing, a "ladder" arrangement of the intestinal coils may be seen through the abdominal wall. The obstructing mass or distended loop may be felt. If the bowel is strangulated, the abdomen is more tender and rebound tenderness may be present. On auscultation one hears borborygmi in mechanical obstruction; in paralytic ileus, the abdomen is silent.

Routinely a scout X-ray film and an upright film are taken as soon as the physical examination of the patient is completed. While the X-ray film is the single most valuable laboratory method one has in the diagnosis and treatment of intestinal obstruction, if one does not view the roentgenograms in the light of the history and physical findings, the procedure may be more confusing than enlightening. Normally gas is never seen in the small intestine of adults; this is probably due to the small size of the gas bubbles and their intimate mixture with food in the small gut. Up to three years, one sees gas in the small bowel of children by X-ray as a normal occurrence.

In this clinic, cases of simple acute mechanical intestinal obstruction are treated by an indwelling duodenal catheter drainage with constant suction. In such cases suction accomplishes everything that an enterostomy does without the risk of operation. However, the condition of such patients treated conservatively must be constantly watched. The degree of distention must be checked by scout films every 12 hours at the least.

The only patients with small bowel obstruction whom we are afraid not only to treat but also that we may treat conservatively are cases of intussusception and obstruction due to impacted gall stones in the bowel. Since the latter condition is usually associated with a cholecysto-intestinal fistula, the presence of gas in the biliary tree may give a clue as to the obstructing mechanism (Rigler-Borman). In general, if the patient with suspected, simple, acute mechanical intestinal obstruction does not improve with suction applied to an indwelling duodenal catheter, some complication is present and one should not temporize too long with conservative measures. In such cases, the patient should have an abdominal exploration: If an adhesive band is found, simple cutting of the band may suffice. However, if the bowel is markedly distended, whether or not the obstructing mechanism is found, it is usually best to perform just an enterostomy. In intestinal obstruction, the importance of asepsis in the technique of enterostomy has been stressed by Wangensteen. At this clinic, the enterostomy tube is left in situ for 10-12 days in most cases of ileus; on removing it, the sinus tract closes promptly. About four to six weeks after the patient has recovered from the intestinal obstruction, a gastro-intestinal study is performed, giving barium sulfate by mouth. If no intrinsic pathologic process is found and the most likely cause of the ileus was intraperitoneal adhesions, no further surgical treatment is advised. However, if this patient has repeated attacks of ileus, an abdominal exploration and enterolysis may be in order.

In strangulating obstructions and occlusions of the colon, conservative therapy is contraindicated. To be certain, one cannot always tell what the exact obstructive mechanism is, but from the history, physical findings, and X-ray evidence, one is usually able to tell: 1, if there is an obstruction present, 2, whether the obstruction is simple or strangulating in character, and 3, whether the large or small bowel is involved. To those of us who have been schooled in the uses and limitations of suction siphonage in the treatment of intestinal obstruction, there is no doubt that in physiologic obstructions and incomplete mechanical ileus due to adhesive bands suction applied to an indwelling duodenal catheter is far superior to any surgical procedure. In other obstructions where the diagnosis is not so certain, while the employment of suction may be used, disaster may follow if constant vigilance is not given to changes in the patient's condition.

APPENDICITIS

A. *Experimental studies.* In 1847, Gerlach described an inconstant semilunar fold of mucous membrane guarding the appendico-cecal orifice. Buirge and Wangensteen in a study of 526 specimens found that while folds may be present around this orifice, there was no indication of a sphincter muscle at the site of union of the appendix and cecum.

Wangensteen and Bowers found that there is a fecolith in the lumen of the appendix in about half the cases of acute appendicitis. The possibility that appendicitis is a form of intestinal obstruction was at once suggested. However, the fact that only about half the cases of acute appendicitis showed signs of organic obstruction suggested that other factors,

possibly functional obstruction, might cause acute appendicitis.

Wangenstein, Buirge, Dennis and Ritchie found that the vermiform appendix exhibits a definite resistance to luminal perfusion. This resistance depends on the amount of circular muscle in the wall and the diameter of the lumen; also, it varies from hour to hour and can be modified by certain drugs. Adrenalin tends to stop the contractions of the appendix, while atropine, benzydine and papaverine have an inconstant effect. Morphine tended to raise the basal pressure and increased the frequency of the smaller waves but decreased their size. B-methyl acetyl choline increased the size and frequency of the small waves as well as raised the basal pressure.

The above authors also found that the obstructed appendix may secrete 1-2 cm. of fluid a day. The nature of the fluid is still obscure. Of the laboratory animals studied so far, only in the rabbit is obstruction of the cecal appendage accompanied by the secretion of the fluid. In fact, in the rabbit, in 10-14 hours, the intraluminal pressure of the appendix obstructed by a ligature increases so much, due to fluid production, that rupture occurs. When croton oil is administered by gavage or hypertonic saline solution injected intravenously, rupture of the obstructed appendix of the rabbit occurs in a much shorter time.

Knowing that the appendix may become easily obstructed, that the appendix does secrete fluid, and from our knowledge of closed-loop obstruction, the pathogenesis of acute appendicitis becomes clearer. The effects of age and the minute anatomy of the appendix as they bear on the problem of acute appendicitis are discussed by Wangenstein et al.

B. Conservative treatment of certain forms of appendicitis.

At this clinic all uncomplicated cases of acute suppurative appendicitis are treated by immediate appendectomy. However, if there are signs of localized abscess or generalized peritonitis, it is our practice to treat such patients conservatively and operate when the acute infection is well subsided (8-10 weeks later). If the patient has been sick for 3-4 days, his temperature over 101°, the pulse over 120 per minute, and the clinical findings not entirely confined to the right lower quadrant, he most likely is treated conservatively, although each case has to be individualized and no hard or fast rules can be made. If the patient comes in with a well localized abscess in the right lower quadrant the patient is treated conservatively; if the mass gets smaller, the conservative treatment is continued; however, if the mass gets larger or the temperature fails to return to normal after three or four days, the abscess is drained. No attempt is made to remove the appendix until 2-3 months later.

The mortality of our cases of appendicitis treated conservatively and surgically have been summarized by Myrick and Sperling. In our hands, cases of ruptured appendix with abscess formation or generalized peritonitis have responded best when treated conservatively. Particularly in certain cases of appendicitis in children has this proven true. Adams and Baneroff of the Pediatric Department of this hospital found that of 110 cases of ruptured appendicitis with abscess formation or generalized peritonitis in children

under 14 years, treated conservatively, only 5 died (4.5%).

LARGE INTESTINE

A. *Diagnosis and treatment of large bowel obstruction.* Colonic obstructions differ both clinically and in their treatment from those of the small bowel. Patients with large bowel obstruction rarely vomit until late in the disease; aspiration of the stomach contents in these patients does not reveal gastric retention or fecal regurgitation as in small bowel ileus. The danger in colonic obstruction is that if complete the segment proximal from the obstruction to the ileocecal valve acts as a closed loop (Sperling) and may perforate at its weakest point, the cecum. These patients should not be treated solely by suction applied to an indwelling duodenal tube but by a preliminary colostomy.

In obstructions of the colon, a marker (a five-cent piece) is fastened to the umbilicus by adhesive tape and a scout film of the abdomen is taken. The marker gives an idea of the location of the obstruction as well as serves as a unit of measure. To decompress the bowel, a transverse incision to the right or left of the upper midline of the abdomen is made; this approach is preferred as the exploration of the whole colon is easier. The colon will present itself directly into the wound, and evisceration is less likely to occur. At this clinic since the above procedure has been used, there has been a great improvement in the operative mortality of colonic obstructions. If the obstructing carcinoma should be in the region of the sigmoid, a secondary operation of the Bloch-Mikulicz type will have to be performed later.

B. *Prolapse of the rectum.* In the treatment of prolapse of the rectum, Wangenstein has found a modification of the Whitehead operation for hemorrhoids to be most satisfactory. With the patient in the lithotomy position, the rectum is allowed to prolapse to its fullest extent. Just proximal to the mucocutaneous junction, a circular incision is made excising only the mucosa to the apex of the prolapse. The mucosa at the apex is then sutured to that near the mucocutaneous juncture. In the few cases done to date, the results have been very satisfactory.

C. *Posterior excision of colon carcinoma.* For carcinoma of the colon below the peritoneal reflection, the procedure in this clinic has been largely to perform a left inguinal colostomy and later do a posterior excision of the lesion. For lesions 6-8 cm. above the peritoneal reflection the posterior excision has often been done where others would have preferred the abdomino-perineal operation. Removal of these higher lesions can often be done from below even though the procedure is somewhat time-consuming and without the far greater risk of the combined operation.

PRE- AND POST-OPERATIVE CARE

A. *Prophylaxis against peritonitis.* In operations upon the stomach, the importance of having the stomach empty has been stressed. The night before operation, an indwelling suction catheter is inserted through the nostril and left in the stomach so that the stomach will be empty at the time of operation. Also, the patient is encouraged to sip dilute hydrochloric acid through a glass tube (10 cc. N HCl in 200 cc.

water). Cultures taken from the stomach through the nasal tube have been found to be sterile for as long as

1½ hours after taking the acid. The value of this procedure as a prophylaxis against peritonitis is apparent.

At the time of operation, the opened bowel surfaces are swabbed with sodium ricinoleate 1%, and at the end of the operation, three or four ounces of this solution are often left in the peritoneal cavity. Experimentally, we have found this solution to be a better germicide and to prevent adhesions more often than ether, amfetin, papain, etc.

B. *Prophylaxis against post-operative complications.* After most laparotomies, the patient is encouraged to move his arms and legs frequently and to turn from side to side as a prophylaxis against thrombophlebitis and hypostatic pneumonia. Also as a preventative against atelectasis, holding the costal margin of the patient and encouraging him to cough is invaluable. Hyperventilating with CO₂ and O₂ mixtures has been discontinued because of the expense, lack of uniformity in administration, and because the above procedures are simpler and more effective. Breathing into a paper bag held tightly against the face is also an effective means of hyperventilation. Thyroid extract is not used here as a prophylaxis against thrombophlebitis; in fact thrombophlebitis has been seen to develop spontaneously in cases of severe hyperthyroidism. To prevent post-operative parotitis, the patient is encouraged to use mouth wash, suck lemons and chew gum. If parotitis develops, the use of hot packs to the involved region seems to be just as effective in our experience as radiation therapy or the oral administration of Lugol's solution.

C. *Use of suction applied to an inlying duodenal tube.* We have come to use suction siphonage by nasal catheter in many conditions other than intestinal obstruction. For instance, it is used preoperatively in all cases of surgery of the stomach or bowel, and in cases where a collapsed gastro-intestinal tract facilitates the operative procedure as splenectomy, operations on the pancreas, ventral hernioplasty, etc. Post-operatively, it is invaluable in the treatment of paralytic ileus. After two surgical procedures the onset of paralytic ileus is particularly insidious: thoracoplasty and the application of a body case in hyperextension. It has been our experience on the Chest Surgical

service that if immediately after thoracoplasty the patient has a high pulse and low blood pressure, he is in shock, but if he has a high pulse but normal blood pressure, he may have acute gastric dilatation.

In the conservative treatment of ruptured appendix, suction applied to an indwelling duodenal catheter tends to keep the small bowel empty, thereby preventing paralytic ileus as well as more contamination of the peritoneal cavity. Also, there is a better chance for the inflammatory process to be walled off as the bowel is quiet.

In ulcer patients with night pain, suction applied to an indwelling gastric tube lessens the pain by removing the hydrochloric acid from the stomach.

The question arises as to how long one may use suction siphonage. Suction has been applied to an indwelling duodenal catheter (inserted through the nostril) for as long as 7-10 days continuously and as long as 23 days intermittently. The patients suffer little discomfort except for sore throat which can be relieved by gargles or 10% cocaine topically applied to the throat. The fluid intake and output of all patients with duodenal suction must be carefully computed, making sure the patient has a positive fluid balance. The plasma chloride must be maintained by intravenous saline solution, and the plasma proteins by blood transfusions. The ionic equilibrium in patients being treated by suction siphonage is being investigated by Paine and Armstrong. The possibility of constructing a tube to both feed and aspirate the patient has been suggested.

SUMMARY

The above review is a broad rather than a detailed survey of our present diagnostic methods and forms of treatment. An attempt has been made to present time-proven rather than "new" procedures. The result of further study and clinical experience will undoubtedly modify many of them.

Some of the commoner problems of gastro-enterology as the etiology of peptic ulcer, pathogenesis of gall stones, prevention of peritonitis, etc., still await final solution. Periodic reviews and the interchange of ideas between various clinics will do much to clarify these problems.

The Management of a Permanent Colostomy*

By

LEONARD J. DRUCKERMAN, M.D.
NEW YORK, NEW YORK

THE proper management of colostomies will enable the majority of patients to forget the discomforts of an abdominal anus for more than twenty-three hours a day. In cases in which the artificial anus is in the cecum, ascending or transverse colon, this is neither easily nor often achieved. Fortunately, however, most permanent colostomies are located on the left side and permit this comfortable state to be readily attained. The return to normal life may be so complete that one may be acquainted with an individual for years and yet never be cognizant of the fact that he has an abdominal anus. People in all walks of life have resumed their usual occupations. There are others, however, less fortunate, who lead miserable existences in constant fear that an unexpected movement may embarrass and inconvenience them and betray their misfortune to all about them. Many of these patients can be rehabilitated economically and socially, but ignorance of that possibility, or the method of its accomplishment, or both, keep them from the physical and mental comfort that should be theirs.

Differences of opinion exist among physicians as to the proper methods of controlling the preternatural anus. Many rely solely on the colostomy bag; others prefer absorbent dressings which are changed as often as necessary. Many and varied gadgets have been invented in an attempt to "cork up" the colostomy for periods of time. Some physicians purge their patients one day and depend upon the resultant temporary constipation to keep their patients comfortable. Great stress has been placed on training the patient to form a regular bowel habit, on diet, on irrigation, and on all three combined.

In the follow-up clinic of the colonic service at The Mount Sinai Hospital, an attempt was made to determine the best methods of caring for the colostomy patient and to establish a standard routine procedure. The knowledge acquired in the care of this type of patient and a review of the more recent literature is the subject matter of this paper. The discussion follows under six headings:

(1) Diet, (2) Medication, (3) Irrigation and training, (4) Use of appliances and dressings, (5) Care of the skin, (6) General measures.

1. DIET

Diet undoubtedly plays the major role in the proper management of a colostomy. The object of dietetic control is to obtain a constipated patient who will have an evacuation only on taking an irrigation. The diet prescribed should produce a stool which is hard, dry, formed, and scant in amount. We have found the most successful diet to be the bland low residue diet with low fat and high carbohydrate components.

Any food which has an irritating action on the stomach or bowel should be avoided. Condiments,

alcohol in any form, iced drinks and charged water, all of which may produce gastro-intestinal disturbances and hyperactivity, are not permitted. Certain foods such as prunes and apricots are forbidden because of their laxative action. Any food which cannot be considered bland should at first be deleted from the list of edible foods.

The diet should be low in residue and foods which produce bulk in the stools must be scrupulously avoided. The vegetables and fruits permitted should be well cooked to render the cellulose as soft and as thoroughly digestible as possible. Initially, these should be pureed. Any food which is indigestible, such as the seeds of berries and the tendinous parts of meat, should never be taken because of the irritating residue.

The low fat diet is employed because it has been found to be the most constipating. Schmieden (1) limits fats until the colostomy is functioning satisfactorily. Hesse (2) believes that intestinal action may be stimulated by a diet rich in fats and accordingly he also limits fats. Cattell (3) starts his patients with a bland diet, low in fat, and later includes a moderate amount. Dubois (4) suggests that at first all foods containing considerable fat should be avoided. In spite of the fact that these patients have lost considerable weight which they should regain and although difficulty may be encountered in administering high caloric meals without the inclusion of fat in the diet, we believe it beneficial to start with the low fat diet. The advantages of comfort and cleanliness resulting from proper bowel control more than counterbalance the difficulties and disadvantages of the diet. Furthermore, the administration of a high carbohydrate diet augmented by chocolate, cocoa, and sugared drinks during meals will increase the caloric intake sufficiently to result in a substantial gain in weight if all other factors are conducive to this.

We have not routinely attempted to limit the fluid intake of our patients. Schmieden and Hesse do so in an effort to produce dry and more constipated stools. We have not found this limitation necessary in left sided colostomies, but it may occasionally be a useful adjuvant in the care of a right-sided or transverse colostomy. There is no doubt also that within certain limits, less food will produce less stool. For this reason Dubois (5) recommends abstinence as being of great advantage in simplifying the care of a colostomy. We, however, have found it unnecessary to limit the quantity of food, and encourage the patient to eat enough to maintain an excellent state of nutrition. Limitation of food and fluid may be attempted occasionally in the obstinate case which does not respond favorably to the usual means of control.

Regular meals and a complete abstinence from food between meals should be the rule. The patient who nibbles at food between meals is most likely to be the one who finds small amounts of stool on the dressing several times a day. Whenever practical, water should

*From the Surgical Service of Dr. Ralph Colp, The Mount Sinai Hospital, New York, N. Y.

be taken only at meal time inasmuch as it may incite the gastrocolic reflex.

THE INITIAL COLOSTOMY DIET

The following foods are recommended:

Vegetables—Cooked vegetables with soft cellulose. (Potatoes, carrots, squash). Vegetable puree. (Peas, beets, string beans, tomatoes, asparagus tips).

Fruits—Cooked fruits with skins and seeds removed. (Apple, pear, peach). Strained juices. (Orange, grapefruit, tomato).

Breads and Cereal—White bread and plain crackers. Cooked fine cereals. (Cream of wheat, pabulum, patent barley, rice). Ready-to-serve cereals without bran. (Corn flakes, puffed wheat). Spaghetti, noodles, macaroni. Plain cake without icing.

Dairy Products—All milk must be boiled. Swiss and American cheese. Small amounts of butter. Eggs—Boiled or poached.

Meats—Tender, well cooked meat, fish and chicken. Fat and tendinous parts should be avoided.

Desserts—Cake or fruit as above. Clear fruit jelly. Simple bland desserts. (Cornstarch, chocolate or tapioca pudding. Custard, junket, plain gelatin).

Miscellaneous—Cocoa, chocolate, weak tea. Caffeine-free coffee or postum if necessary.

The following foods should be avoided:

Vegetables—All vegetables except those listed above. Any raw vegetable. Irritating vegetables. (Onions, peppers, radishes). Vegetables high in residue.

Fruits—Raw fruits. Fruits high in indigestible cellulose. (Pineapple). Fruits containing many seeds. (Berries).

Breads and Cereals—Whole grain breads. (Whole-wheat and pumpernickel). Cereals high in residue. (Bran cereals, wheatena).

Dairy Products—Cream, cheeses other than those listed above.

Meat—Pork, veal or duck. Skins of poultry. Fatty and fibrous parts of meat.

Miscellaneous—Fried foods of any kind. Jams. Spices and condiments. Highly seasoned or strongly salted foods. Coffee, strong tea, charged water, alcohol in any form.

A typical diet follows:

Breakfast—Fruit juice or fruit. Well cooked cereal with boiled milk and sugar. Eggs. White bread or toast with butter or jelly. Cocoa or chocolate.

Dinner—Tomato juice. Meat, fish or chicken. Boiled, baked or mashed potato. Pureed vegetables as listed. Fruit or pudding. White bread or toast. Cocoa or tea.

Supper—Milk soup with strained vegetables or clear soup. Meat or cheese or eggs. Vegetables. Custard or pudding or gelatin. White bread or toast with butter or jelly. Cocoa or tea.

Shortly after the desired degree of constipation is obtained, new foods may be cautiously added. Only one new food should be given over any two day period, so that if it is deleterious, it can be immediately recognized and subsequently avoided. Individuals differ markedly in their reactions to food. Certain people will be constipated regardless of what they eat, whereas others may have a profuse diarrhea for twenty-four hours following the ingestion of a raw apple. There is a certain group of patients who have been constipated all their lives and who continue to remain so after operation. This group may eat almost

anything after a time without untoward effects on colostomy function. There are others whose frequency of bowel movement directly reflects the foods eaten. Proper diet will adequately constipate this group. There is still a third group who normally have two to three bowel movements daily. After operation this group presents a difficult problem and requires careful dietetic management, supplemented by proper medication, for the attainment of a well controlled colostomy.

The first change usually permitted is the serving of the whole cooked vegetable instead of the puree. This change may be made at a relatively early period. Later, raw skinned fruits and a greater variety of vegetables are added, and if these are tolerated well, cream or uncooked milk may be used in the cereal and tea. The allowance of butter is increased and the fatty parts of meat are given if desired. Fried foods are added last, if at all. Foods such as cabbage, celery, poultry skins and others which have an irritating or bulky residue should never be permitted except in those cases in which the degree of constipation is so marked that any food may be taken without materially affecting the bowel function. Additions are continued until the patient is receiving the maximum number of foods that is compatible with the desired degree of constipation. It is obvious that the ultimate diet will vary greatly in different patients because of their individual reactions to foods.

2. MEDICATION

Although most of our patients lead comfortable colostomy lives without the aid of constipating medications, there are certain patients who require them and are materially benefited by their use. The patient with a transverse colostomy who despite careful attention to diet still has loose stools, may be greatly helped by the proper medicines. The nervous individual often requires constipating medication and small doses of sedatives for successful regulation. The judicious use of drugs is indicated when patients are first attempting to constipate themselves. Finally, they may be temporarily necessary after a dietary indiscretion.

Bismuth subcarbonate in doses of 15 to 60 grains, three times a day, is valuable in inducing constipation or allaying diarrhea. Dubois states that not only does it tend to make the stool more solid but also renders them odorless. It also diminishes the amount of gas in some patients. Powdered kaolin, a somewhat less constipating medication, may occasionally be used along with, or instead of the bismuth.

Opium is very often efficacious when other drugs fail, but it should be used over relatively short periods of time. It may be administered simultaneously with other medications. The two most used preparations are tincture of opium in doses of five, ten, or twenty minims, three or four times daily, and paragoric in teaspoonful doses at like intervals. The amount of morphine administered is relatively small, the former containing 1/10 of a grain of morphine in each 10 minims, and the latter containing 1/40 of a grain of morphine to each four cubic centimeters.

Charcoal is often advised as a remedy for excessive amounts of gas. Sollmann (6) claims that whereas freshly heated charcoal adsorbs gasses, moist charcoal does not possess this quality and that it is,

therefore, unsuccessful in the treatment of flatulence. Schmieden reports that it not only rids the patient of gas but also deodorizes the stools. Hesse speaks highly of animal charcoal for similar reasons. We have found that finely divided and dried vegetable charcoal occasionally reduces the amount of gas. It is administered in doses of 15 to 30 grains three times a day.

The use of Kerol to deodorize the excreta is recommended by Lockhart-Mummery (7) Shedden (8) and Best (9). A capsule containing 3 minims is given daily before breakfast.

Laxatives and purgatives are mentioned only to be condemned. They are rarely needed and do not fit into our scheme of the proper management of a colostomy. Constipation is the state we attempt to produce so that defecation of feces will occur every two or three days and then only under the stimulation of an irrigation. No one who has spent several hours with a colostomy patient suffering from diarrhea will need to be cautioned against the use of purgatives.

Occasionally one sees left-sided colostomy patients who do not respond to the constipating diet and medications. These patients may be suspected of having so called gastrogenous diarrhea due to achylia gastrica. Diagnosis is made of course by a fractional test meal. Rehfuess (10) states that even small amounts of hydrochloric acid will succeed in overcoming this diarrhea. The dilute hydrochloric acid may be used in liquid, capsule, or tablet form.

It is recommended that those patients who require a strict constipating diet over long periods of time be given concentrated vitamins, especially vitamin D to augment the scant vitamin content of the diet.

3. IRRIGATION AND TRAINING

Irrigations are of the utmost importance in the care of a colostomy. There are in the literature scattered reports about a chronic colitis that occurs following a long continued use of irrigations. Most observers, however, find irrigations an excellent procedure in the management of a colostomy and see no ill effects from its long continued use. Binkley (11) states that daily irrigation of colostomies has been in vogue for many years at the Memorial Hospital in New York and that experience has proven this procedure to be by far the most satisfactory method. Cattell, Smith (12), Bowman (13), and others, employ irrigations routinely. We have had excellent results from the irrigation treatment of colostomies and have so far never seen ill effects. The object of the irrigation is to thoroughly empty the colon of its fecal content so that no movement will occur during the intervals between irrigations. The length of these intervals is determined by trial and error. It will be found that patients who are chronically constipated prior to operation will often be able to allow two or three days between irrigations. This may also be true for those who are able to achieve a marked degree of constipation by means of diet and medication. Constipation in patients with colostomies has not been found to be detrimental to the general health. The average patient requires an irrigation about once in twenty-four hours. We employ the simplest possible technique. An ordinary enema bag or can is equipped with a tube, a shut-off valve, a glass adapter and a 26 F. catheter. Warm tap water is used for the irrigation which may be given with the patient sitting, standing, or lying

in bed. The enema can is placed about three feet above the level of the colostomy, the catheter is inserted into the colostomy as far as it will go, and the water is allowed to flow in slowly. A large deep basin is held snugly against the abdomen just below the colostomy to catch whatever may run back along the catheter. Sometimes it is necessary to hold a piece of gauze or cotton tightly against the lumen of the bowel to prevent too much loss of water. When the patient feels quite full, the catheter is removed and the water and intestinal contents are expelled into the basin. When all the water and stool have seemingly been expelled, the entire procedure is repeated once or several times until the return is clear. About ten to twenty minutes are allowed to elapse before the permanent dressing is applied because during this time fluid temporarily retained in the colon will be discharged. A small piece of gauze and a large thick cellulocotton or cotton pad is placed over the stoma to absorb the fluid as it is expelled. Later the permanent dressing is applied. Further attention is usually not required for the ensuing twenty-four hours.

This is the so-called "open" method of irrigation. With a little care and practice it can be performed with no soiling of the body, clothes, or room. The average time required is about forty-five minutes. The only parts of the apparatus requiring cleaning are the catheter and basin. There is, however, a "closed" method of irrigation for which numerous devices have been invented. Best (14) employs a metal urinal which has a tube running into it near the handle and out through the mouth of the urinal. This tube is inserted into the colostomy, the urinal is held firmly against the abdomen over the stoma, and the water is allowed to flow through the tube, wash out the colon and run back into the urinal. Binkley uses an excellent apparatus for closed irrigation. It consists of a bakelite cup which has a small opening for a catheter and a wide outlet which connects with a broad soft rubber tube. The cup is held in position over the stoma by an adjustable canvas belt. The apparatus can be used with the patient lying in bed or sitting on toilet. The irrigating fluid is run into the colon through the catheter and the returning fluid and feces is expelled into the cup and conveyed through the wide rubber tube into a receptacle or into the toilet unseen by the patient. Binkley has found this method so satisfactory that he uses it routinely.

For the fastidious or sensitive patient, one or another of these appliances may be found very useful. The advantage of the closed method lies solely in its aesthetic appeal. Its disadvantages are: the apparatus itself must be cleaned, the irrigation takes longer, and the continuous irrigation with the catheter in place does not clean the bowel quite as well as the intermittent flushing and emptying.

There is a small percentage of patients who do not need to employ irrigations but are able to have a regular movement every morning and remain perfectly clean for the remainder of the day. Many more patients are able to have the regular movement but tend to have several very small movements during the day. Gibson (15) prefers irrigation to training. Lockhart-Mummery attempts to train his patients to have regular movements before inaugurating irrigation treatment. Schmieden and Hesse advocate training. Webb (16) employs small irrigations at

first for the purpose of establishing habitual morning evacuations. The individual who is fortunate enough to have this automatic function is to be encouraged provided that he is able to remain perfectly clean for a full day between movements. The method of starting this movement varies with the individual. Some find that the thought of a movement is sufficient to initiate it; others find that a glass of cold water or hot coffee, or a cigarette may cause the bowel to function. In our experience very few patients are able to remain perfectly clean for twenty-four hours without irrigations.

4. USE OF APPLIANCES AND DRESSINGS

Colostomy bags are rarely prescribed. They are never employed for left-sided colostomies but are used exclusively in the occasional cecostomy or transverse colostomy when these cannot be controlled by the usual methods because of the impossibility of obtaining solid stool. The use of colostomy bags for left-sided colostomies is fast falling into disrepute. Almost all who have written upon this subject attempt to discourage their use. The colostomy bag is a highly unsatisfactory appliance which is difficult to clean and to keep clean. It is usually expensive and requires frequent renewal because of the offensive, musty, odor which the rubber retains and emanates. It causes irritation of the stoma and the surrounding skin and deforms the normal contour of the patient. Binkley, Gabriel and Lloyd-Davies (17), Best, Landsman, (18) and others call attention to the frequent abdominal wall weaknesses and ventral herniae seen about the stoma among those who are addicted to colostomy bags. It is not certain whether these are caused by ischemia from the pressure of the rim of the bag, or whether it is due to the suction effect of the bag. The protrusion of the bowel all too frequently seen in these cases, is due to the suction effect and presumably the more frequent movements are likewise attributable to the same cause. There is no doubt that prolapse and ventral hernia occur among those who do not wear colostomy bags, but the incidence is very much less. Furthermore, we have seen patients develop both hernia and prolapse months after discharge from the hospital after they were fitted with a colostomy bag by their physicians. Prior to this they had repeatedly been examined in the follow-up clinic and found to have neither hernia nor prolapse. It is also true that a low grade inflammation of the exteriorized mucous membrane is often seen in patients wearing colostomy bags. The thick mucus that is discharged constantly from these colostomies is very distressing and quite frequently produces a dermatitis of the surrounding skin. One needs only to watch the offensive messy spectacle of a patient changing and cleaning the bag in order to be thoroughly disgusted with it. Colostomy bags should never be used except as a last resort when all else fails.

For the few unfortunates who require a colostomy bag, it is advisable to secure one possessing several important qualities. It should be, if possible, inexpensive so that a new one may frequently be obtained. The cup fitting over the stoma should have a small diameter so as not to produce herniae. The straps should be detachable and washable. The contrivance

should be relatively flat in order that it may not cause too great a bulge and distortion of the patient's figure. It is sometimes helpful to insert gauze or cellulocotton into the colostomy bag, to absorb the fluid and so make the wearer more comfortable and the cleaning easier. Whenever possible, the physician himself should select the bag.

The simplest possible dressing is employed. After the temporary dressing previously described is removed, it is replaced by the permanent dressing. The exposed bowel is covered with a strip of gauze on which boric acid ointment or vaseline has been applied. Another piece of gauze is placed over this and a pad of cotton or cellulocotton is then applied. Some patients like to have "lap straps" on either side of the abdomen to tie over this; others merely wear their supporting belts. A piece of oiled silk may be interposed between the belt and the dressing. Most patients wear a belt and all are encouraged to do so. A simple belt made of elastic webbing is often quite satisfactory. These are inexpensive and are usually made by the patient. They have some tendency to roll at the sides and are at times productive of post-prandial pressure and discomfort. An adjustable abdominal support made of knitted elastic, narrow over the sides and back, and broad in front, with two or three pliable vertical supports anteriorly, has been found most satisfactory. Some patients have in addition, a simple elastic belt or muslin binder which is used at night.

5. CARE OF THE SKIN

The usual left-sided colostomy causes a negligible amount of skin irritation and little, if any, care of the skin is necessary. Occasionally, however, the skin will become inflamed and even ulcerated. This is seen far more often in the presence of cecostomies than in any other large bowel neostomy. In the prevention and treatment of dermatitis, any ointment which adequately protects the skin from the irritant to which it has been subjected may be used. The ointment we have found to be the most efficacious is made of ten per cent zinc oxide and ten per cent finely powdered aluminum in anhydrous lanolin. This is applied on the thoroughly cleaned and dried skin all about the stoma and the usual dressings applied. It is of great importance that the patient keep watching for the first signs of dermatitis, because when it is moderately advanced, it is quite difficult to cure. It is advisable to use an ointment constantly if the stoma discharges liquid stool, irritating stool or much mucus.

Occasionally patients report bleeding from the stoma. Closer questioning will often disclose that the blood was seen to issue from the junction between the skin and mucous membrane. Inspection reveals some granulation tissue which is easily and successfully treated by the application of strong silver nitrate solution.

Rarely a patient will return with some stenosis of the colostomy opening. A moderate degree of stenosis without definite retraction of the loop of bowel leading to the opening is not harmful and should merely be kept under observation. If the contraction continues, it may become necessary to dilate the opening manually or with bougies, preferably after the infiltration of novocaine. If, however, there is a marked degree

of stenosis, with or without retraction of the spur, surgical therapy is indicated.

6. GENERAL MEASURES

Before discharge from the hospital, the patients are taught how to irrigate themselves. Upon leaving the hospital they are given printed directions for the proper method of open irrigation, a list of foods to be eaten, a list of foods to be avoided, and a typical diet. Some patients are visited at their homes by a nurse who instructs the patient and some member of the family in matters appertaining to colostomy care.

At first, patients visit the clinic at short intervals, and diet and regime changes are made as indicated. After the patient is well regulated, he is seen at intervals of four to six months. He is weighed, his general condition is noted, a search for distant metastases is made, and the colostomy is carefully inspected for local recurrence, stenosis, retraction of the spur, prolapse and hernia.

Some patients are able to exercise violently without encountering any difficulty, whereas others may have a small movement after moderately severe exertion. It is necessary to determine the patient's reaction to

exercise by trial and error and to act accordingly. Most patients do this by themselves a short time after discharge from the hospital.

Individualization is the key note of success in the management of a colostomy. Patients vary in their approach to the problem of colostomy life just as they vary in their reactions to other problems. One patient will accept the colostomy calmly and follow instructions willingly, whereas another will speak of suicide, refuse to do anything connected with his care, and require an attendant for months after his wounds have healed. The methods which may be applied on the first patient can never be employed on the second. Each patient must be considered as an individual problem and the routine varied accordingly. The mental attitude of the patient must be considered and carefully schooled in the proper channels. Infinite tact and patience are required in caring for these patients to whom the colostomy comes as a severe shock and a loathsome disfigurement. In time, with proper guidance of thought and action, the colostomy may become just another one of the many burdens that the individual patiently carries with him throughout life.

Notes on a Trip to Scandinavian Countries and London

By

MANDRED W. COMFORT, M.D.*
ROCHESTER, MINNESOTA

SCANDINAVIAN COUNTRIES

COPENHAGEN.—One of my most valued experiences was making the acquaintance of Prof. Knud Faber. Dr. Faber is seventy-six years of age and has now retired. He has been, and still is, one of the outstanding medical figures in the Scandinavian countries. He retains his interest in things medical and is head of the Dansk Tuberkuloselaegeselskab. He has shown that the increased incidence of tuberculosis during the World War was inversely related to the supply of foods such as meat and butter.

He first published his observations on gastritis in 1898, and he has been responsible for placing gastritis on a firm pathologic basis. He does not believe that the term "hypertrophic gastritis" is important unless actual polypoid changes are present. He stated that the symptomatology of superficial, ulcerative gastritis

resembles that of peptic ulcer, and in his hands the treatment has been much the same. He uses lavage with salt water and sometimes hydrogen peroxide if other measures do not cure. My impression was that he does not regard atrophic gastritis or gastritis with anacidity as such a clear-cut clinical entity as superficial ulcerative gastritis. He believes the symptoms are largely owing to associated disturbances in the function of the bowel—particularly constipation—and he directs much of his treatment to care of the bowel. He uses dilute hydrochloric acid, not so much because he feels that there is need for replacement therapy but because the patient seems often to progress better when it is given.

Professor Faber is opposed to the use of surgical measures in cases of ulcer if it can be avoided because he has seen so many patients who were worse after surgical intervention.

*Division of Medicine, The Mayo Clinic.
Submitted June 29, 1935.

Commune Hospital. Here, I made the acquaintance of Prof. H. I. Bing, who is a charming man of sixty-six. He has a great deal of enthusiasm and was spoken of with affection by physicians in Copenhagen. He very courteously showed me his hospital which was built about 1866. He is physically fit and never rides in an automobile. He still rides his bicycle at a fast clip and some time after I left the hospital he proudly overtook me, remarking that there was a lot in the old man yet.

Professor Bing is a physician of the old school and believes strongly in the practice of clinical medicine in preference to laboratory medicine. His extraordinary skill in the art of percussion and palpation was obvious, and its development has constituted one of his major interests. From this has developed his observations on what he terms "viscerocutaneous or axonal" reflexes. He demonstrated for me by percussion the contracture of the colon and of the stomach following irritation of the skin overlying these organs, and of the changes in location of the borders of the lung following scratching of the skin of the thoracic wall.

I remarked that the art of examining the patient by percussion and palpation as he had demonstrated it was fast becoming a lost art. He laughed and said, "Yes, I often say that I am the last of the Mohicans!"

In Professor Bing's clinic I was happy to meet his assistant, Dr. Thune Anderson. Anderson has made important observations on the etiology of epidemic jaundice and has most interestingly shown that the epidemic and endemic types of jaundice are related to a comparable disease occurring in hogs. He has transmitted the disease from hog to hog by feeding infected livers, and he has transmitted it from man to hog by feeding to the hog bile obtained by drainage from patients with epidemic jaundice. This observation on the etiology of epidemic jaundice is an important one to the Danes, who fear that it may well affect the export of bacon to England, one of their main sources of revenue. This problem is receiving the attention of the medical profession as well as of economists of the country.

Bispebjerg Hospital. Here, I saw Prof. E. Meulengracht, who is best known in this country for the Meulengracht test or the icterus index, and because he has advocated immediate feeding of patients with bleeding peptic ulcer. Actually it is unfortunate that most of the physicians of this country do not know that they owe the icterus index to Meulengracht. His wards are well run, and it would be well worth while for anyone going to Copenhagen to visit them. He still believes in feeding the patient who has a bleeding ulcer. I saw many of these patients in his wards and they certainly seemed to be doing just as well as do those of our patients who are given a limited diet. From the moment these patients enter the hospital he gives them five good-sized meals of puréed foods a day, and any amount of fluid they desire. As a result of this treatment, he feels that the period of convalescence has been shortened and dehydration and emaciation have been avoided. He also believes that he has lowered the mortality rate to 1 or 2 per cent. He stated, however, that the differences in mortality rates in different countries might be owing to the fact that there may be differences in the severity of the lesions. Certainly, the severity of the hemorrhage in his wards was not great.

Meulengracht has made contributions to the problem of pernicious anemia. He showed that the anti-anemic principle is to be found chiefly in those parts of the stomach and duodenum which are lined by the cardiac glands, the pyloric glands, and the glands of Brunner. Recent study of the duodenums of patients with pernicious anemia has shown, however, that Brunner's glands are well preserved. Professor Meulengracht is not able to explain this unless it be that these glands supply an inadequate amount of the intrinsic principle.

Meulengracht believes that the treatment of peptic ulcer is primarily a medical problem, and surgical measures are seldom resorted to. Gastro-enterostomy is then the operation of choice.

Amtssygehuset Genofte is one of the county hospitals. It is a relatively new hospital. The medical service here was in charge of Dr. Tage Christiansen, and the type of medicine being practiced certainly was as good as that seen in any of the teaching city and university hospitals. Dr. Christiansen is energetic and has a forceful personality. Christiansen follows Schindler in his conception of gastritis. He thinks that gastritis begins in the fundus and spreads distally; that superficial, ulcerative gastritis responds well to treatment and that the hypertrophic form may or may not be associated with ulceration. He thinks that in a small percentage of cases this superficial ulcerative gastritis goes over into the atrophic form. He believes that gastritis and gastric ulcer are two distinct diseases etiologically and pathologically.

One of my reasons in looking up Dr. Christiansen was because of his interest in and knowledge of pancreatic disease and of pancreatic function. His studies were begun with the hope of developing a method for the diagnosis of pancreatic disease. He used predigested food as a stimulant, but finally concluded that while his work was of physiologic interest it did not have wide application clinically, because of the variability in results brought about by mechanical factors incident to duodenal distention.

Christiansen agreed with Dr. Meulengracht that the treatment of ulcer was primarily a medical affair and he resorts to surgery in only a few cases. Then gastro-enterostomy is the operation of choice.

Stockholm.—On my arrival in Stockholm I got in touch with Dr. I. Holmgren. He is now professor emeritus, but he still maintains many of his old interests. He is editor of the "Acta Medica Scandinavica" and has been in a great measure responsible for the fact that medical papers are now being written in English; this gives the Scandinavian writers a much wider influence in the world. Many of the English and American textbooks of medicine are now being used in Sweden without translation.

Serafimer Lasarettet Hospital. Professor Holmgren arranged for me to meet Prof. Nana Svarts, who is in charge of the medical service at this hospital. Ordinarily, there are two professors of medicine in Stockholm, but at the present time Professor Svarts is the only one because of the recent death of Professor Jacobæus. Dr. Svarts is a woman and so far as is known, is the only woman in the world who is a professor of medicine.

She has long been interested in fermentative diarrheas, which she treats with autogenous vaccine and colonic irrigations composed of a weak solution of kollargol, together with a low carbohydrate diet. She

has also been interested in ulcerative colitis and has found a variety of organisms in the stools. A diplococcus has been found, but she does not feel that this is the only organism responsible for the disease. She treats patients with a vaccine, a high carbohydrate, high fat and somewhat bland type of diet, irrigations with kollargol, and the usual vitamins. Many cases of this disease are sent to her for treatment.

Dr. Svarts stated that in the treatment of arthritis they do not place the same emphasis on focal infection as we do in this country. The treatment of hyperthyroidism differs somewhat from that used here. Surgical operation is resorted to when the patient is young and radiation is employed later in life. The results of roentgenologic treatment are said to be good.

On Dr. Svarts' service the diagnosis of gastritis is based on the visualization of the mucosal pattern by roentgenologic methods. Nothing new is being used in the treatment of the condition. Again, peptic ulcer is looked on as a medical disease, the indications for surgical measures being "three cures, two hemorrhages, or one episode of obstruction." The operation of choice for many years has been gastric resection, usually of the Billroth II type. Professor Svarts, however, felt that there was a distinct tendency now to go back to gastro-enterostomy.

One of the chief things I wanted to find out while in Stockholm was something about the value of peritoneoscopy. Professor Jacobaeus, who died last year, had used this for many years. Dr. Svarts stated that his enthusiasm for this method of examination had waned during the years and that during the last five years of his life he had used it only in cases of ascites, wherein he wanted to determine the cause in liver or peritoneum. His enthusiasm for the thoracoscope did not wane; he used it for cutting adhesions preparatory to collapsing the lung in cases of tuberculosis and for localizing tumors.

Sankt Eriks Sjukhus Hospital. Prof. Hilding Berglund is in charge of the fourth medical service at this hospital. His service is well organized and he has as his assistants, Dr. Bengt Ihre, Dr. Henrik Lagerlöf and Dr. A. Rune Frisk.

Dr. Ihre has shown that small amounts of hydrochloric acid can be demonstrated in almost every case of apparent achlorhydria if continuous suction of the gastric contents is carried out following the injection of histamine. He has also shown that when the vagus nerves are stimulated by giving 16 units of insulin intravenously, the injection of histamine, intramuscularly, will produce some secretion of some free hydrochloric acid in an even greater percentage of apparently achlorhydric patients. Ihre is also studying gastric acidity in its relation to gastritis. He thinks that there are variations depending on the condition of the mucous membrane. Dr. Ihre has been doing gastroscopy for some time and has much skill in this technic.

The dietary management of the bleeding gastric or duodenal lesion is usually a liberal one in Stockholm just as it is in Copenhagen.

If the patient is not vomiting, food and fluids are given freely. The treatment of peptic ulcer is again thought to be essentially medical.

Dr. Lagerlöf has been responsible for the clinical application of secretin in the study of pancreatic function. At Dr. Berglund's suggestion he carried out a test for me, and showed that secretin obtained from

animals will produce a flow of pancreatic juice in man. By using a double tube with one opening in the stomach and the other in the duodenum, he prevented gastric secretion from entering the duodenum and secured almost pure pancreatic juice, at least from those patients with a competent sphincter of Oddi. Secretin increases especially the volume and the alkaline content of the pancreatic juice. On the other hand, the concentration of the enzymes is more markedly influenced by stimulation of the vagus nerves by insulin or pilocarpine. Food likewise increased the concentration of enzymes in the juice. Dr. Lagerlöf agreed that probably in the future, it will be found best in testing pancreatic function to use secretin and pre-digested food together as stimulants. He insisted, however, that the use of secretin alone could disclose major and minor variations in the functional and secretory capacity of the pancreas.

ENGLAND

It is always stimulating to visit the great London hospitals.

London.—Guy's Hospital. Sir Arthur Hurst's Tuesday afternoon clinic was attended. Two cases were of especial interest; the first was one of chronic intussusception of an adult in examination of whom a sausage-like tumor could be palpated in the right upper quadrant of the abdomen. There had been a long history of intermittent obstruction. The second case was one in which malnutrition was the chief symptom. The patient had undergone gastrojejunostomy many years previously. After repeated roentgenologic examinations, a gastroduodenal fistula was demonstrated. Exploration had revealed only a very small, sinus-like tract, the narrowness of which explained the difficulty the roentgenologists had had in demonstrating its existence. Sir Arthur believed that the long pre-operative preparation of the patients was a factor in the low mortality rate which he attains in these cases. He cleans out the bowel and uses a low residue diet.

Hammersmith Hospital. This is a part of the University of London postgraduate Medical School. The medical service under Professor Fraser and Reader Aitken is excellently organized. A case of multiple, tuberculous strictures of the bowel with a blood picture of pernicious anemia was presented as an illustration of the rôle which defective absorption can play in the production of macrocytic anemia. A full-blown case of scurvy was also seen with, strange to say, a negative tourniquet test.

Hospital of Tropical Diseases. Dr. M. Hamilton Fairley showed many interesting cases of sprue and atypical avitaminosis. In his experience, tropical sprue responds much more favorably to the administration of liver extract than does nontropical sprue. Dr. Fairley's pathologic studies on cases of sprue have led him to discard the theory that atrophy of the mucous membrane is responsible for the lack of absorption of fat and proteins in this condition.

Note: It is always interesting to hear at first hand what's new medically in foreign countries, and it is particularly interesting to hear from a traveler and particularly from a traveling gastro-enterologist whose interests are our own. Because of this we would be happy to publish from time to time in the columns of this Journal, interesting accounts of medical observations made abroad.

Dr. Mandred Comfort has just returned from Europe, and I have asked him to tell us here briefly of his experiences in the Scandinavian countries and in London.

—The Editor.

A Leader in Gastro-enterology Says . . .

"The recent advances in gastro-enterology have been of such magnitude and distinction that they engender in us a just pride and renew our determination to press forward toward our goal of perfection."

Dr. Ernest H. Gaither, Baltimore, Md., in his address at Kansas City before the section on gastro-enterology and proctology of the A.M.A.

The American Journal of Digestive Diseases

- Now in its fourth year of publication—without alteration in its fixed principle of giving to the reading members of the medical profession the contributions of the best clinicians and investigators in the United States, Canada and Europe.
- So formulated, and edited by one of the most capable and select editorial groups in contemporary medical journalism, the Journal has made unusual progress during the comparatively short period of publication . . . today, the editorial office is constantly in receipt of very valuable manuscripts which collectively form a cross section of new gastro-enterological thought.
- The absence of "politics" from this set-up ensures to the reader an unbiased preliminary evaluation of submitted material by men pre-eminently qualified to judge the worth of MSS in the various sub-fields of this broad specialty.
- Meeting the growing difficulty of prompt publication, the Journal is constantly diminishing its back log of material by insistence more and more, as time goes on, upon the idea of BREVITY in writing.
- The American Journal of DIGESTIVE DISEASES is not only making friends but it is KEEPING friends. The renewal percentage each year and each month is a positive proof of the sound, month-by-month value of the publication, and it is recognized that this Journal provides today, as no other publication ever provided, a trustworthy postgraduate education in a field much more intricate and fascinating than has been generally supposed.
- Once upon a time gastro-enterology was generally regarded as a specialty contaminated by faddism and quackery, but the pioneers, many of whom are still living and active on this editorial board have lifted it to the level of a strictly ethical study—and the Journal is playing an important role in facilitating this important branch of medical practice.

VITAMINS IN RELATION TO GASTRO-INTESTINAL DISEASES	Martin G. Vorhaus, M.D.
STUDIES ON THE PARALLEL ACTION OF VITAMIN C AND CALCIUM	Simon L. Ruskin, M.D.
THE PASSAGE OF GALL STONES THROUGH THE SPHINCTER OF ODDI	Marie Ortmyer, M.D. and Margaret Austin, M.D.
INFRA-RED PHOTOGRAPHY OF THE ABDOMINAL WALL IN PORTAL CIRRHOSIS OF THE LIVER	I. R. Jankelson, M.D. and Henry Baker, M.D.
THE EFFICIENCY OF SEVERAL GERMICIDES AND ANTISEPTICS ON THE ORAL MUCOSA	Esther Meyer, Ph.G., M.S. and Lloyd Arnold, M.D.
PRIMARY CARCINOMA OF THE LIVER	Abel Levitt, M.D., F.A.C.P. and Dexter S. Levy, M.D.
THE USE OF HYDRATED MAGNESIUM TRISILICATE IN PEPTIC ULCER (PRELIMINARY REPORT)	Manfred Kraemer, M.D., F.A.C.P.
VARIATIONS IN THE LEVEL OF SERUM LIPASE IN EXPERIMENTAL PANCREATITIS	Hamilton Baxter, M.D., Stewart G. Baxter, M.D. and John F. McIntosh, M.D.
COD LIVER OIL PER RECTUM AS AN ADJUNCT IN THE TREATMENT OF ULCERATIVE COLITIS	R. Russell Best, M.D.
THE RELATIONSHIP OF THE DIET TO THE SELF-REGULATORY DEFENSE MECHANISM. I. HYDROGEN-ION CONCENTRATION AND BACTERIAL FLORA	Nicholas P. Sullivan, M.S. and Ira A. Manville, M.D., Ph.D.
HEALTH AND NUTRITION OF HIGH ANDEAN INDIANS	Clarence William Lieb, A.M., M.D.

An Open Letter to the Physicians of North America

Do you realize that 60 per cent of all symptoms in general practice arise from the digestive tract?

Many diseases are intrinsic, and many at a distance reflect their symptomatology with great facility in the alimentary canal . . .

Is diagnosis of digestive diseases easy?

Apparently not. The old rule of thumb—"appendix, ulcer, or gall bladder" is no longer useful. We are becoming gradually acquainted with the disorders and diseases of the colon and reducing this information to some semblance of order. Physiology, bacteriology, chemistry, parasitology, clinical observation, animal experimentation, roentgenology, nutrition, allergy and psychology are the organized methods of approach to a fuller knowledge of

digestive diseases. And there still lies beyond, the dark continent of the small intestine, concerning which so little is positively known.

To the scholar, what is offered by this Journal is indispensable.

To the man too busy to indulge his yen for applied research, may we say this—an hour a month with the American Journal of DIGESTIVE DISEASES will provide the key to practical success in this most important, difficult, but "treatable" field.

Spend \$6.00 for a year or \$10.00 for 2 years NOW. Join the increasing group of doctors who enjoy this periodical. The card below is attached for your use, and is postage free.

ANNOUNCEMENT

AFTER the death of Doctor Smithies, the American Journal of Digestive Diseases carried on somewhat experimentally under a board of four editors. Although these individuals worked devotedly, they were much handicapped by not having a chairman to direct and correlate their work.

To repair this defect Doctor Cornell and the American Gastro-Enterological Association have now agreed that there be an editor-in-chief, acceptable to both contracting parties and working always in close cooperation with the Council of the Association, to take control of the editorial and advertising policies. This seemed to be the surest way of attaining the end so much desired by both Doctor Cornell and the Association, namely, the building of the Journal into as fine, dignified, scientific, and practically useful a magazine as it is possible to make.

This means that while Doctor Cornell's office will continue to be responsible for the financing of the Journal and its assembling, printing and mailing, the supplying of material for it is now up to all of us in America who are interested in the problems of digestion. All can work to build up this Journal, and all can take pride in what success is later attained. As the new editor, I can succeed only with your help and support. I am to be your servant, and especially during this first year I shall need and welcome your suggestions and criticisms.

As in the past, so even more in the future, the object of the Journal will be to supply helpful information on gastro-enterologic topics to physicians, surgeons, physiologists, laboratory workers, teachers of medicine, proctologists, dietitians, and all others who are interested in the problems of nutrition both in health and disease.

This Journal will continue to welcome manuscripts from anyone with a new and interesting message. Every effort will be made to keep short the interval between the reception of a manuscript and its appearance in print. We hope to have more articles and shorter ones, and we hope to present several times a year reviews of what is being done in the gastro-enterologic field in other lands. We hope also to publish in these pages reports of work of interest to gastro-enterologists that is done by men outside our ranks in physiology, surgery, dietetics, pediatrics and roentgenology.

Walter C. Alvarez, Rochester.

DR. A. C. IVY GETS THE GOLD MEDAL AT THE MEETING OF THE AMERICAN MEDICAL ASSOCIATION IN SAN FRANCISCO

ALL gastro-enterologists who for years have watched with interest the stream of valuable papers that have come from Dr. Ivy's laboratory in the Northwestern University Medical School will rejoice at his award of the Gold Medal given by the American Medical Association for the best exhibit presented at the recent meeting in San Francisco. The medal might well have been awarded for any one of several of Ivy's important discoveries of gastro-enterologic interest,

but actually it was given because of his production of hermaphroditic or intersexual rats by the prolonged injection into the pregnant mothers of large amounts of the newly isolated sex hormones. A study of the remarkable combinations of male and female characteristics in the pelvic organs of these animals must throw great light on the ways in which the sexual organs differentiate and develop in the normal male and female.

Another recent achievement of Dr. Ivy and his students was the demonstration that the removal of the stomach from growing puppies produces a severe homogenous osteoporosis. The animals become bowlegged, much as in rickets, but the disease is not rickets and it appears in spite of the fact that the animals are given plenty of calcium and vitamin D.

The deficient ossification seems to be due to three factors: (a) the absence of hydrochloric acid, which normally helps in the absorption of calcium from the bowel; (b) the loss of the reservoir function of the stomach and the resultant speeding of food transport through the bowel, and (c) the presence of a postcibal acidosis, or acid tide, which tends to decrease the retention of calcium (Bussabarger, Freeman and Ivy, A. J. P., 121:137-148, 1938).

Walter C. Alvarez, Rochester.

A NEW IDEA IN THE TREATMENT OF ULCER

AT the recent meeting of the American Medical Association in San Francisco, one of the most interesting and thought stimulating papers and exhibits was by David J. Sandweiss, H. C. Saltzstein and A. Farbman, from the Harper Hospital and the Medical Department of Wayne University, in Detroit. Doctor Sandweiss noticed that women with ulcer commonly lose their symptoms when they become pregnant. Searching through the literature, he and his associates found that this had been observed by a number of men. A review of 70,000 consecutive hospital records of pregnant women showed only one case in which note was made of an active ulcer. There were many notes made, however, of concomitant appendicitis and cholecystitis. In a group of forty-six women with ulcer studied carefully, it was found that only one had active symptoms of ulcer during pregnancy. Several of the women commented on the fact that the coming of pregnancy would always heal their ulcer. A rather high percentage of the women with ulcer were thought to have some signs of endocrine disturbance.

The possibility occurred to Sandweiss that the hormones found in the urine of pregnant women might be responsible for this beneficial action of pregnancy on ulcer. About 100 dogs were prepared according to the Mann-Williamson technic in which the duodenum is drained into the lower ileum and the first segment of jejunum is anastomosed to the pylorus. Of forty control animals, all died with large typical jejunal ulcers after an average of fifty-eight days. In 70 per cent of these control animals the ulcer perforated. Fifteen of these dogs were injected with theelin, which

seemed to aggravate the ulcer so that perforation and death took place more quickly than usual.

Forty dogs were then injected with the anterior pituitary-like hormone from the urine, and on the average these survived over 100 days. In 50 per cent of the animals necropsied there was no sign of ulcer, and in half of the remainder there were histologic signs of healing in the ulcer. In only about 15 per cent of the treated dogs did the ulcer perforate. When one remembers that Mann-Williamson dogs usually succumb to a perforated ulcer within two or three months, it is remarkable that seven of the forty dogs treated are still alive and well, most of them nearly a year after the operation.

Sandweiss and his coworkers then inactivated the anterior pituitary-like hormone by heating it four hours at 90° C. and injected ten Mann-Williamson dogs with this inactivated extract. Nine of these animals died with the typical jejunal ulcers.

The next question that occurred to Sandweiss and his associates was whether the urine of normal persons contained the protective substance. Actually, when the urine of normal, nonpregnant women was extracted according to the technic used in preparing the anterior pituitary-like substance, and when this extract was used in the treatment of ten dogs, it also was found to be protective. The workers then made a similar extract from the urine of men and women with ulcer, but when this was injected into Mann-Williamson dogs it seemed to do harm, and the ulcers became more destructive to life.

Sandweiss, Saltzstein and Farbman are careful to point out that because of the small number of animals used for the last described experiments, they cannot

yet be certain about the results; they are only suggestive.

Walter C. Alvarez, Rochester.

NEW HOPE FOR THE EPILEPTIC

ONE of the most hopeful and interesting announcements made recently is that of Drs. H. H. Merritt and T. J. Putnam of Boston, who have found a drug which is much more efficient in quieting the brain and preventing convulsive seizures than are the ones previously available. These workers took advantage of the fact that by certain operative procedures they can produce a disease in the cat which much resembles epilepsy. Using these cats as test objects, they tried one chemical substance after another until they found some that controlled the convulsions better than did bromides and phenobarbital. The best drug found in this way was diphenylhydantoin.

They now report that in 77 per cent of patients with a severe type of epilepsy, tested with the drug, the seizures were either completely prevented or else reduced in frequency. Very fortunately the drug is able to quiet the brain enough to prevent the attacks without at the same time causing unpleasant drowsiness.

Doubtless the drug will now be tried out extensively with the hope of relieving many other conditions in which the brain is abnormally irritable, and everyone will be keenly interested to see the results of these tests. If the usefulness of this new drug should prove to be as great in the hands of everyone as it has been in the hands of Drs. Merritt and Putnam, they will have earned a most honorable place in the hall of fame.

Walter C. Alvarez, Rochester.

Book Review

Chronic Intestinal Toxemia and its Treatment. By James W. Wiltsie. Baltimore, William Wood and Co., 268 pp., 1938.

MANY a gastro-enterologist has doubtless wondered if there is anything of value in the treatment of so-called chronic intestinal toxemia with colon lavage done in the office with special apparatus. Most men are predisposed against the procedure because it is based on an ancient theory of medicine which has been dragged out time and again in the last 4,000 years, only to be thrown back repeatedly into the junk room of medicine, and of course into the hands of irregular practitioners and laymen. It does seem that if the method had any real value it should have established itself in practice years ago.

Actually, this little book by Wiltsie seems to be the best written and best documented apology for colon washing that has as yet appeared. It is written by an earnest man with an M.D. after his name, obviously a man who wants to do the right and the scientific thing, and who has no sympathy with quackery. As he says on page 4, "The rather prevalent tendency to ridicule the use and users of colon irrigations naturally dampens the interest of anyone who otherwise might feel inclined to study their value. One brave enough to use them is apt to be regarded as either a fool or a knave. He is held under suspicion, ignored and avoided."

Unfortunately, as so often happens, the physician who goes against the better judgment of his fellows, gets to feeling that they are influenced and bound solely by taboos. As Wiltsie says: "It is surprising what influence a professional taboo of this nature has upon the mental processes of the individual members. They do not seem to be able to think independently or reason logically. Rather than accepting their training and education as an emancipation of thought, and feeling free to use their knowledge in constructive ways, they are restrained by authority and fear of ridicule. However, there is no place for creeds in medicine; but having satisfied the fundamental requirements of an adequate knowledge of the medical sciences, all that is required of us in the practice of our profession is intellectual honesty, moral integrity, and mature judgment."

After this statement, the reader will be the more inclined to reject the teachings of the book if he finds that Wiltsie is living and working by a creed, and if he finds him dodging and saying nothing about all the important facts that are against his theory.

Usually, a wise, well-trained physician with a large experience and good clinical judgment can tell after a quick look through a paper or a book whether or not the writer had the clinical and scientific judgment to walk warily in the narrow path between science and

pseudo-science. He can judge the author in a minute by the quality of his case reports, and he will damn him promptly if it is obvious that with his pet procedure he was trying to cure everything under the sun, or that while busy washing the colon, he failed to note that the patient had a gall bladder full of stones or an ulcer, or a manic depressive insanity, or just a plain, everyday neurosis. Thus, recently, the reviewer happened to see a patient who had had his colon washed strenuously for months by a well-known man with an M.D. after his name. It was not surprising that the patient didn't get well, seeing that his trouble was not in his colon but in his head. If the physician had been less busy colon-washing he would have noted the slight paralysis of the face, the slight aphasia, and the complete character change that followed a stroke.

Many of Wiltzie's case reports show that he realizes that every disease cannot be cured by irrigations, which is a tremendous step forward for a colon washer. Unfortunately, Wiltzie is not clear as to what the syndrome of chronic intestinal toxemia is. As he says on page 6, "Since this syndrome is not a well-defined entity, but presents different pictures in different individuals, pathognomonic signs and symptoms are not to be expected. The condition must first be suspected, then proved or disproved. If it is present we shall have little difficulty in checking the findings as of intestinal origin. In addition to purely subjective evidence, we may find anemia, abnormal blood-pressure, increased blood sedimentation rate, increase of the conjugated end-products of intestinal putrefaction in the urine, loss of weight, catarrhal conditions of the mucous membranes, specific blood agglutinins, etc. Singly, or in twos and threes, these findings mean nothing, but linked with others commonly found, the history of the case, subjective symptoms, etc., the presumption that our suspicions are justified will increase as the evidence multiplies. Improvement under therapeutic test forms the final link in our diagnostic chain."

One suspects from this that pretty nearly anything can be accepted by the colon washer as grist for his mill.

On page 18 Wiltzie says, "In all chronic toxemias and infections *I now proceed on the assumption that the colon is invariably involved*, (Italics are the reviewer's. This book looks a bit like a creed) and treat it regardless of the presence of other foci. In actual practice I have demonstrated, at least to myself, that it is better practice to treat the colon before attempting the removal of other known foci, since many of these will clear up spontaneously as soon as the colon is functioning normally."

This, of course, reveals the author as a bit more enthusiastic about his method than most gastro-enterologists could bring themselves to be. One could easily go through the book and show many instances of weak reasoning or of the quoting of scripture to a purpose. Many things Wiltzie says are self-evident would be pretty hard to prove to most physicians.

Another way in which one can quickly judge of a man's good sense and general trustworthiness is by watching to see how he chooses the authors whom he

quotes, and whether he quotes with equal confidence the pronouncements of unscientific men, whose work is not accepted by the medical profession, and of able and revered leaders in fields of research. Actually, Wiltzie would have greatly strengthened his argument by not quoting certain men as approvingly as he does.

The next question asked by the reader who is trying to form an opinion of an argument is: Did the writer face squarely every bit of evidence that was against his theory or did he ignore it? In this case, one immediately looks through the book to see if there is any adequate discussion of those scores of research articles on auto-intoxication which were summarized and evaluated in 1924 for "Physiological Reviews." How does Wiltzie face these many reports of laboratory investigations, nearly all of which failed to support the theory of intestinal auto-intoxication? Unfortunately Wiltzie does not even mention this outstanding article in his bibliography.

It has always been a puzzle to the reviewer what the difference is between an enema given to herself by a patient at home, and an irrigation given by a quack or a doctor in his office, and hence we are particularly disappointed in that the book does not clear up our doubts on this point. There must be a huge difference because one reads on page 234 the astounding statement that "the use of enemas during or following a series of irrigations should be strictly forbidden, not only because a pernicious habit may be acquired, but also because there is nothing better calculated to upset everything that colonic therapy is endeavoring to accomplish"! One would think from this that the most important thing Wiltzie could do is to show his readers exactly why an enema given at home is so dangerous and harmful and why one given in the office is so beneficial. We searched through the book for more light on this, the most important problem raised by the author but failed to find it.

There is some help on page 109, where Wiltzie quotes from Bastedo to the effect that, "the term irrigation conveys the idea of washing; therefore, while the ordinary enema is given with the purpose of inducing defecation, the irrigation is administered, not to induce defecation but to wash out material situated above the defecation area and to lavage the wall of the bowel as high as the water can be made to reach." This helps, but still we are left a little puzzled.

Of course, all theories aside, the final test of any method is what it can do. One must expect many persons to feel better while the colon is being kept clean but it is hard to see why there should be any permanency in the results after the irrigations are stopped.

If there is one disease which colonic irrigation might conceivably help, it should be chronic arthritis, but it would seem that Wiltzie's results in this field have been poor, because instead of bragging about them, he quotes from the writings of others, and suggests the use of vaccines.

We have here, then, a book written with much devotion and with more clinical acumen than is met with in most colon washers. But still the reviewer is not convinced that it would pay him to put in a colon washing table. Perhaps he is just getting old and "set in his ways."

Pohl, in 1737, gave a fairly accurate description of prostatic calculi. As late as 1838, Civalé stated: "Their origin is very dark; they have not been studied accurately enough so that it can be said under what pathological conditions they are formed, nor what

organic changes lead to their formation."

Biliary peritonitis of obscure origin was first reported by Saunders, in 1783. A fourteen year old boy, after falling from a tree was bled and purged for four days because of severe pains in the abdomen. His abdomen gradually enlarged and on the twenty-fourth day two gallons of

bile was removed through a trocar. On the thirty-seventh day he was again tapped. The trocar entered the intestine and he died of peritonitis five days later.

Drainage of the abdominal cavity as now practiced was developed after McDowell began performing ovariectomies. It was found in most of the fatal cases a collection of serosanguinous fluid formed in the pelvis.

Drainage through the cul-de-sac was first attempted by Keith, in 1864. He also introduced intraperitoneal drainage through the rectum. Celsus, so far as is known, first drained the abdomen for the removal of ascitic fluid. His tubes were made of lead and brass and tapered to prevent slipping into the abdomen. Galen, in the second century, and Avicenna, in the eleventh, used the same technique as Celsus.

Adenoma of the liver in young infants suggests the congenital origin of these tumors. Wagner, in 1861, described such an instance in a nursing.

The first detailed description of fibrous osteoma of the jaw was published by Menzel, in 1872. The tumor was noted by the patient over a period of twenty-five years. It was removed because of partial obstruction of the air and food passages.

Bennett, in 1881, exhibited before the Dublin Pathological society a series of fractures of the metacarpal bones. Such fractures are recognized as Bennett's fracture.

John Hunter transplanted cocks' spurs into their combs. The spurs grew to an enormous size. He attributed the excessive growth to inflammation, believing that an increase in the blood supply stimulated healing by giving power of action.

Diverticulosis of the colon was described by Cruveilhier, in 1849, Virchow in 1853, by Rokitsansky in 1856. These investigators are usually given credit, however, Ballies' Morbid Anatomy published in 1794, recognized sacculations of the colon.

Trephining for depressed fractures of the skull was done in ancient Egypt. Hippocrates observed that fractures with depression were not particularly dangerous unless the membranes were ruptured.

Lanza and Higgins were the first Americans to make a comprehensive report on silicosis. The disease is not a recent one for Ramazzini, in 1700 described the condition.

Richter, in 1778, gave a complete scientific description of a hernia which now bears his name. Treves

For Dehydration -- Alka-Vess

The loss of water from the tissues which is so frequently symptomatic of summer diarrheas and other hot weather affections tends to carry with it a depletion in alkali and mineral reserves.

You can meet this deficiency successfully and in a convenient, pleasant form for your patients by prescribing Alka-Vess.

Each tablet contains the buffer salts calcium-di-hydrogen phosphate 3 grs.; potassium bicarbonate 1 gr.; magnesium sulphate (dried) 1 gr.; sodium chloride 1 gr.; citric acid 19 grs.; sodium bicarbonate 31 grs.

In convenient tubes of 25 tablets.

suggested that this type of hernia be called Richter's hernia to differentiate it from the hernia of Littre.

WHYTE, DAVID AND O'REGAN, ROLLAND
Complete Prolapse of the Rectum.
New Zealand Med. Jour., 36:381-382, Dec., 1937.

The injection method of treatment of rectal prolapse is not entirely safe. A case is reported in which sloughing of the rectal wall occurred with severe and repeated secondary hemorrhage. Temporary colostomy and six blood transfusions in the course of seventeen days were considered necessary in treatment. The end result was complete cure.

CARMALT-JONES, D. W.

Disorders of the Pituitary Gland in Relation to Circulatory and Metabolic Disturbances. Med. Jour. of Australia, 1:439-440, March 5, 1938.

Anterior pituitary excess leads to overgrowth, hypertension increase in basal metabolic rate, with at present an imperfectly traced influence on the other endocrine glands. No medication is of any service in these cases. A defect of the anterior lobe of the pituitary leads sometimes to wasting, sometimes to obesity and a low basal metabolic rate. Patients with these conditions may be capable of treatment with anterior pituitary extracts. Water metabolism is controlled by the hypothalamus and posterior lobe of the pituitary, and persons suffering from excessive loss of water may be treated by posterior pituitary extract.

Placenta accreta, a comparative rare condition was known to the older obstetricians. Morgagni made mention of the condition and commented that it was difficult even with a bistoury, to separate the placental tissue from the uterine muscle.

Ried, of Erlangen, a German surgeon, was the first to recognize tuberculosis of the flat bones of the vault of the skull. His article appeared in 1842, however, the cases were observed in 1838.

Carcinoma of the male breast was mentioned in the writings of Arcaeus (1493-1573). Hildanus (1537-1619) described a similar case. It was not until 1872 that a systematic study of this disease was made by Horteloup.

Le Gallois, in 1812, Knox in 1839, and Barlow in 1854, reported rupture of the symphysis pubis articulation in parturient guinea pigs, seals and cows.

Hahn in 1881, conceived the idea of sewing the perirennal fat to the walls of the lumbar incision. He named his procedure nehrorrhaphy.

In 1870, Gilmore made the deliberate and successful effort to remove a kidney during pregnancy.

The first case of iliopectineal bursitis was reported by Fricke of Germany, in 1834. Joly, in 1847, recognized the second case.
